## APPROXIMATE DYNAMIC PROGRAMMING

## A SERIES OF LECTURES GIVEN AT

## TSINGHUA UNIVERSITY

JUNE 2014
DIMITRI P. BERTSEKAS

Based on the books:
(1) "Neuro-Dynamic Programming," by DPB and J. N. Tsitsiklis, Athena Scientific, 1996
(2) "Dynamic Programming and Optimal Control, Vol. II: Approximate Dynamic Programming," by DPB, Athena Scientific, 2012
(3) "Abstract Dynamic Programming," by DPB, Athena Scientific, 2013
http://www.athenasc.com
For a fuller set of slides, see
http://web.mit.edu/dimitrib/www/publ.html

## APPROXIMATE DYNAMIC PROGRAMMING

## BRIEF OUTLINE I

## - Our subject:

- Large-scale DP based on approximations and in part on simulation.
- This has been a research area of great interest for the last 25 years known under various names (e.g., reinforcement learning, neurodynamic programming)
- Emerged through an enormously fruitful crossfertilization of ideas from artificial intelligence and optimization/control theory
- Deals with control of dynamic systems under uncertainty, but applies more broadly (e.g., discrete deterministic optimization)
- A vast range of applications in control theory, operations research, artificial intelligence, and beyond ...
- The subject is broad with rich variety of theory/math, algorithms, and applications. Our focus will be mostly on algorithms ... less on theory and modeling

## APPROXIMATE DYNAMIC PROGRAMMING

## BRIEF OUTLINE II

- Our aim:
- A state-of-the-art account of some of the major topics at a graduate level
- Show how to use approximation and simulation to address the dual curses of DP: dimensionality and modeling
- Our 6-lecture plan:
- Two lectures on exact DP with emphasis on infinite horizon problems and issues of largescale computational methods
- One lecture on general issues of approximation and simulation for large-scale problems
- One lecture on approximate policy iteration based on temporal differences (TD)/projected equations/Galerkin approximation
- One lecture on aggregation methods
- One lecture on Q-learning, and other methods, such as approximation in policy space

# APPROXIMATE DYNAMIC PROGRAMMING 

## LECTURE 1

## LECTURE OUTLINE

- Introduction to DP and approximate DP
- Finite horizon problems
- The DP algorithm for finite horizon problems
- Infinite horizon problems
- Basic theory of discounted infinite horizon problems

## DP AS AN OPTIMIZATION METHODOLOGY

- Generic optimization problem:

$$
\min _{u \in U} g(u)
$$

where $u$ is the optimization/decision variable, $g(u)$ is the cost function, and $U$ is the constraint set

- Categories of problems:
- Discrete ( $U$ is finite) or continuous
- Linear ( $g$ is linear and $U$ is polyhedral) or nonlinear
- Stochastic or deterministic: In stochastic problems the cost involves a stochastic parameter $w$, which is averaged, i.e., it has the form

$$
g(u)=E_{w}\{G(u, w)\}
$$

where $w$ is a random parameter.

- DP deals with multistage stochastic problems
- Information about $w$ is revealed in stages
- Decisions are also made in stages and make use of the available information
- Its methodology is "different"

## BASIC STRUCTURE OF STOCHASTIC DP

- Discrete-time system

$$
x_{k+1}=f_{k}\left(x_{k}, u_{k}, w_{k}\right), \quad k=0,1, \ldots, N-1
$$

$-k$ : Discrete time

- $x_{k}$ : State; summarizes past information that is relevant for future optimization
- $u_{k}$ : Control; decision to be selected at time $k$ from a given set
- $w_{k}$ : Random parameter (also called "disturbance" or "noise" depending on the context)
- $N$ : Horizon or number of times control is applied
- Cost function that is additive over time

$$
E\left\{g_{N}\left(x_{N}\right)+\sum_{k=0}^{N-1} g_{k}\left(x_{k}, u_{k}, w_{k}\right)\right\}
$$

- Alternative system description: $P\left(x_{k+1} \mid x_{k}, u_{k}\right)$

$$
x_{k+1}=w_{k} \quad \text { with } P\left(w_{k} \mid x_{k}, u_{k}\right)=P\left(x_{k+1} \mid x_{k}, u_{k}\right)
$$

## INVENTORY CONTROL EXAMPLE

- Discrete-time system

$$
x_{k+1}=f_{k}\left(x_{k}, u_{k}, w_{k}\right)=x_{k}+u_{k}-w_{k}
$$

- Cost function that is additive over time

$$
\begin{aligned}
& E\left\{g_{N}\left(x_{N}\right)+\sum_{k=0}^{N-1} g_{k}\left(x_{k}, u_{k}, w_{k}\right)\right\} \\
& \quad=E\left\{\sum_{k=0}^{N-1}\left(c u_{k}+r\left(x_{k}+u_{k}-w_{k}\right)\right)\right\}
\end{aligned}
$$

## ADDITIONAL ASSUMPTIONS

- Probability distribution of $w_{k}$ does not depend on past values $w_{k-1}, \ldots, w_{0}$, but may depend on $x_{k}$ and $u_{k}$
- Otherwise past values of $w, x$, or $u$ would be useful for future optimization
- The constraint set from which $u_{k}$ is chosen at time $k$ depends at most on $x_{k}$, not on prior $x$ or $u$
- Optimization over policies (also called feedback control laws): These are rules/functions

$$
u_{k}=\mu_{k}\left(x_{k}\right), \quad k=0, \ldots, N-1
$$

that map state/inventory to control/order (closedloop optimization, use of feedback)

- MAJOR DISTINCTION: We minimize over sequences of functions (mapping inventory to order)

$$
\left\{\mu_{0}, \mu_{1}, \ldots, \mu_{N-1}\right\}
$$

NOT over sequences of controls/orders

$$
\left\{u_{0}, u_{1}, \ldots, u_{N-1}\right\}
$$

## GENERIC FINITE-HORIZON PROBLEM

- System $x_{k+1}=f_{k}\left(x_{k}, u_{k}, w_{k}\right), k=0, \ldots, N-1$
- Control contraints $u_{k} \in U_{k}\left(x_{k}\right)$
- Probability distribution $P_{k}\left(\cdot \mid x_{k}, u_{k}\right)$ of $w_{k}$
- Policies $\pi=\left\{\mu_{0}, \ldots, \mu_{N-1}\right\}$, where $\mu_{k}$ maps states $x_{k}$ into controls $u_{k}=\mu_{k}\left(x_{k}\right)$ and is such that $\mu_{k}\left(x_{k}\right) \in U_{k}\left(x_{k}\right)$ for all $x_{k}$
- Expected cost of $\pi$ starting at $x_{0}$ is

$$
J_{\pi}\left(x_{0}\right)=E\left\{g_{N}\left(x_{N}\right)+\sum_{k=0}^{N-1} g_{k}\left(x_{k}, \mu_{k}\left(x_{k}\right), w_{k}\right)\right\}
$$

- Optimal cost function

$$
J^{*}\left(x_{0}\right)=\min _{\pi} J_{\pi}\left(x_{0}\right)
$$

- Optimal policy $\pi^{*}$ satisfies

$$
J_{\pi^{*}}\left(x_{0}\right)=J^{*}\left(x_{0}\right)
$$

When produced by $\mathrm{DP}, \pi^{*}$ is independent of $x_{0}$.

## PRINCIPLE OF OPTIMALITY

- Let $\pi^{*}=\left\{\mu_{0}^{*}, \mu_{1}^{*}, \ldots, \mu_{N-1}^{*}\right\}$ be optimal policy
- Consider the "tail subproblem" whereby we are at $x_{k}$ at time $k$ and wish to minimize the "cost-to-go" from time $k$ to time $N$

$$
E\left\{g_{N}\left(x_{N}\right)+\sum_{\ell=k}^{N-1} g_{\ell}\left(x_{\ell}, \mu_{\ell}\left(x_{\ell}\right), w_{\ell}\right)\right\}
$$

and the "tail policy" $\left\{\mu_{k}^{*}, \mu_{k+1}^{*}, \ldots, \mu_{N-1}^{*}\right\}$

- Principle of optimality: The tail policy is optimal for the tail subproblem (optimization of the future does not depend on what we did in the past)
- DP solves ALL the tail subroblems
- At the generic step, it solves ALL tail subproblems of a given time length, using the solution of the tail subproblems of shorter time length

## DP ALGORITHM

- Computes for all $k$ and states $x_{k}$ :
$J_{k}\left(x_{k}\right)$ : opt. cost of tail problem starting at $x_{k}$
- Initial condition:

$$
J_{N}\left(x_{N}\right)=g_{N}\left(x_{N}\right)
$$

Go backwards, $k=N-1, \ldots, 0$, using

$$
\begin{aligned}
& J_{k}\left(x_{k}\right)=\min _{u_{k} \in U_{k}\left(x_{k}\right)} \underset{w_{k}}{E}\left\{g_{k}\left(x_{k}, u_{k}, w_{k}\right)\right. \\
&\left.+J_{k+1}\left(f_{k}\left(x_{k}, u_{k}, w_{k}\right)\right)\right\}
\end{aligned}
$$

- To solve tail subproblem at time $k$ minimize
$k$ th-stage cost + Opt. cost of next tail problem starting from next state at time $k+1$
- Then $J_{0}\left(x_{0}\right)$, generated at the last step, is equal to the optimal cost $J^{*}\left(x_{0}\right)$. Also, the policy

$$
\pi^{*}=\left\{\mu_{0}^{*}, \ldots, \mu_{N-1}^{*}\right\}
$$

where $\mu_{k}^{*}\left(x_{k}\right)$ minimizes in the right side above for each $x_{k}$ and $k$, is optimal

- Proof by induction

## PRACTICAL DIFFICULTIES OF DP

- The curse of dimensionality
- Exponential growth of the computational and storage requirements as the number of state variables and control variables increases
- Quick explosion of the number of states in combinatorial problems
- The curse of modeling
- Sometimes a simulator of the system is easier to construct than a model
- There may be real-time solution constraints
- A family of problems may be addressed. The data of the problem to be solved is given with little advance notice
- The problem data may change as the system is controlled - need for on-line replanning
- All of the above are motivations for approximation and simulation

## A MAJOR IDEA: COST APPROXIMATION

- Use a policy computed from the DP equation where the optimal cost-to-go function $J_{k+1}$ is replaced by an approximation $\tilde{J}_{k+1}$.
- Apply $\bar{\mu}_{k}\left(x_{k}\right)$, which attains the minimum in $\min _{u_{k} \in U_{k}\left(x_{k}\right)} E\left\{g_{k}\left(x_{k}, u_{k}, w_{k}\right)+\tilde{J}_{k+1}\left(f_{k}\left(x_{k}, u_{k}, w_{k}\right)\right)\right\}$
- Some approaches:
(a) Problem Approximation: Use $\tilde{J}_{k}$ derived from a related but simpler problem
(b) Parametric Cost-to-Go Approximation: Use as $\tilde{J}_{k}$ a function of a suitable parametric form, whose parameters are tuned by some heuristic or systematic scheme (we will mostly focus on this)
- This is a major portion of Reinforcement Learning/Neuro-Dynamic Programming
(c) Rollout Approach: Use as $\tilde{J}_{k}$ the cost of some suboptimal policy, which is calculated either analytically or by simulation

## ROLLOUT ALGORITHMS

- At each $k$ and state $x_{k}$, use the control $\bar{\mu}_{k}\left(x_{k}\right)$ that minimizes in
$\min _{u_{k} \in U_{k}\left(x_{k}\right)} E\left\{g_{k}\left(x_{k}, u_{k}, w_{k}\right)+\tilde{J}_{k+1}\left(f_{k}\left(x_{k}, u_{k}, w_{k}\right)\right)\right\}$,
where $\tilde{J}_{k+1}$ is the cost-to-go of some heuristic policy (called the base policy).
- Cost improvement property: The rollout algorithm achieves no worse (and usually much better) cost than the base policy starting from the same state.
- Main difficulty: Calculating $\tilde{J}_{k+1}(x)$ may be computationally intensive if the cost-to-go of the base policy cannot be analytically calculated.
- May involve Monte Carlo simulation if the problem is stochastic.
- Things improve in the deterministic case (an important application is discrete optimization).
- Connection w/ Model Predictive Control (MPC).

## INFINITE HORIZON PROBLEMS

- Same as the basic problem, but:
- The number of stages is infinite.
- The system is stationary.
- Total cost problems: Minimize
$J_{\pi}\left(x_{0}\right)=\lim _{N \rightarrow \infty} \underset{\substack{w_{k} \\ k=0,1, \ldots}}{E}\left\{\sum_{k=0}^{N-1} \alpha^{k} g\left(x_{k}, \mu_{k}\left(x_{k}\right), w_{k}\right)\right\}$
- Discounted problems ( $\alpha<1$, bounded $g$ )
- Stochastic shortest path problems ( $\alpha=1$, finite-state system with a termination state) - we will discuss sparringly
- Discounted and undiscounted problems with unbounded cost per stage - we will not cover
- Average cost problems - we will not cover
- Infinite horizon characteristics:
- Challenging analysis, elegance of solutions and algorithms
- Stationary policies $\pi=\{\mu, \mu, \ldots\}$ and stationary forms of DP play a special role

# DISCOUNTED PROBLEMS/BOUNDED COST 

- Stationary system

$$
x_{k+1}=f\left(x_{k}, u_{k}, w_{k}\right), \quad k=0,1, \ldots
$$

- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$
$J_{\pi}\left(x_{0}\right)=\lim _{N \rightarrow \infty} \underset{\substack{w_{k} \\ k=0,1, \ldots}}{E}\left\{\sum_{k=0}^{N-1} \alpha^{k} g\left(x_{k}, \mu_{k}\left(x_{k}\right), w_{k}\right)\right\}$
with $\alpha<1$, and $g$ is bounded [for some $M$, we have $|g(x, u, w)| \leq M$ for all $(x, u, w)]$
- Optimal cost function: $J^{*}(x)=\min _{\pi} J_{\pi}(x)$
- Boundedness of $g$ guarantees that all costs are well-defined and bounded: $\left|J_{\pi}(x)\right| \leq \frac{M}{1-\alpha}$
- All spaces are arbitrary - only boundedness of $g$ is important (there are math fine points, e.g. measurability, but they don't matter in practice)
- Important special case: All underlying spaces finite; a (finite spaces) Markovian Decision Problem or MDP
- All algorithms ultimately work with a finite spaces MDP approximating the original problem

## SHORTHAND NOTATION FOR DP MAPPINGS

- For any function $J$ of $x$, denote
$(T J)(x)=\min _{u \in U(x)} \underset{w}{E}\{g(x, u, w)+\alpha J(f(x, u, w))\}, \forall x$
- $T J$ is the optimal cost function for the onestage problem with stage cost $g$ and terminal cost function $\alpha J$.
- $T$ operates on bounded functions of $x$ to produce other bounded functions of $x$
- For any stationary policy $\mu$, denote

$$
\left(T_{\mu} J\right)(x)=\underset{w}{E}\{g(x, \mu(x), w)+\alpha J(f(x, \mu(x), w))\}, \forall x
$$

- The critical structure of the problem is captured in $T$ and $T_{\mu}$
- The entire theory of discounted problems can be developed in shorthand using $T$ and $T_{\mu}$
- True for many other DP problems.
- $T$ and $T_{\mu}$ provide a powerful unifying framework for DP. This is the essence of the book "Abstract Dynamic Programming"

## FINITE-HORIZON COST EXPRESSIONS

- Consider an $N$-stage policy $\pi_{0}^{N}=\left\{\mu_{0}, \mu_{1}, \ldots, \mu_{N-1}\right\}$ with a terminal cost $J$ :

$$
\begin{aligned}
J_{\pi_{0}^{N}}\left(x_{0}\right) & =E\left\{\alpha^{N} J\left(x_{k}\right)+\sum_{\ell=0}^{N-1} \alpha^{\ell} g\left(x_{\ell}, \mu_{\ell}\left(x_{\ell}\right), w_{\ell}\right)\right\} \\
& =E\left\{g\left(x_{0}, \mu_{0}\left(x_{0}\right), w_{0}\right)+\alpha J_{\pi_{1}^{N}}\left(x_{1}\right)\right\} \\
& =\left(T_{\mu_{0}} J_{\pi_{1}^{N}}\right)\left(x_{0}\right)
\end{aligned}
$$

where $\pi_{1}^{N}=\left\{\mu_{1}, \mu_{2}, \ldots, \mu_{N-1}\right\}$

- By induction we have

$$
J_{\pi_{0}^{N}}(x)=\left(T_{\mu_{0}} T_{\mu_{1}} \cdots T_{\mu_{N-1}} J\right)(x), \quad \forall x
$$

- For a stationary policy $\mu$ the $N$-stage cost function (with terminal cost $J$ ) is

$$
J_{\pi_{0}^{N}}=T_{\mu}^{N} J
$$

where $T_{\mu}^{N}$ is the $N$-fold composition of $T_{\mu}$

- Similarly the optimal $N$-stage cost function (with terminal cost $J$ ) is $T^{N} J$
- $T^{N} J=T\left(T^{N-1} J\right)$ is just the DP algorithm

## "SHORTHAND" THEORY - A SUMMARY

- Infinite horizon cost function expressions [with $\left.J_{0}(x) \equiv 0\right]$
$J_{\pi}(x)=\lim _{N \rightarrow \infty}\left(T_{\mu_{0}} T_{\mu_{1}} \cdots T_{\mu_{N}} J_{0}\right)(x), \quad J_{\mu}(x)=\lim _{N \rightarrow \infty}\left(T_{\mu}^{N} J_{0}\right)(x)$
- Bellman's equation: $J^{*}=T J^{*}, J_{\mu}=T_{\mu} J_{\mu}$
- Optimality condition:
$\mu:$ optimal $<==>\quad T_{\mu} J^{*}=T J^{*}$
- Value iteration: For any (bounded) $J$

$$
J^{*}(x)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(x), \quad \forall x
$$

- Policy iteration: Given $\mu^{k}$,
- Policy evaluation: Find $J_{\mu^{k}}$ by solving

$$
J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}}
$$

- Policy improvement: Find $\mu^{k+1}$ such that

$$
T_{\mu^{k+1}} J_{\mu^{k}}=T J_{\mu^{k}}
$$

## TWO KEY PROPERTIES

- Monotonicity property: For any $J$ and $J^{\prime}$ such that $J(x) \leq J^{\prime}(x)$ for all $x$, and any $\mu$

$$
\begin{aligned}
(T J)(x) & \leq\left(T J^{\prime}\right)(x), & \forall x, \\
\left(T_{\mu} J\right)(x) & \leq\left(T_{\mu} J^{\prime}\right)(x), & \forall x .
\end{aligned}
$$

- Constant Shift property: For any $J$, any scalar $r$, and any $\mu$

$$
\begin{aligned}
(T(J+r e))(x)=(T J)(x)+\alpha r, & \forall x, \\
\left(T_{\mu}(J+r e)\right)(x)=\left(T_{\mu} J\right)(x)+\alpha r, & \forall x,
\end{aligned}
$$

where $e$ is the unit function $[e(x) \equiv 1]$.

- Monotonicity is present in all DP models (undiscounted, etc)
- Constant shift is special to discounted models
- Discounted problems have another property of major importance: $T$ and $T_{\mu}$ are contraction mappings (we will show this later)

## CONVERGENCE OF VALUE ITERATION

- For all bounded $J$,

$$
J^{*}(x)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(x), \quad \text { for all } x
$$

Proof: For simplicity we give the proof for $J \equiv 0$. For any initial state $x_{0}$, and policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$,

$$
\begin{aligned}
J_{\pi}\left(x_{0}\right)= & E\left\{\sum_{\ell=0}^{\infty} \alpha^{\ell} g\left(x_{\ell}, \mu_{\ell}\left(x_{\ell}\right), w_{\ell}\right)\right\} \\
= & E\left\{\sum_{\ell=0}^{k-1} \alpha^{\ell} g\left(x_{\ell}, \mu_{\ell}\left(x_{\ell}\right), w_{\ell}\right)\right\} \\
& +E\left\{\sum_{\ell=k}^{\infty} \alpha^{\ell} g\left(x_{\ell}, \mu_{\ell}\left(x_{\ell}\right), w_{\ell}\right)\right\}
\end{aligned}
$$

The tail portion satisfies

$$
\left|E\left\{\sum_{\ell=k}^{\infty} \alpha^{\ell} g\left(x_{\ell}, \mu_{\ell}\left(x_{\ell}\right), w_{\ell}\right)\right\}\right| \leq \frac{\alpha^{k} M}{1-\alpha},
$$

where $M \geq|g(x, u, w)|$. Take min over $\pi$ of both sides, then lim as $k \rightarrow \infty$. Q.E.D.

## BELLMAN'S EQUATION

- The optimal cost function $J^{*}$ is a solution of Bellman's equation, $J^{*}=T J^{*}$, i.e., for all $x$,

$$
J^{*}(x)=\min _{u \in U(x)} \underset{w}{E}\left\{g(x, u, w)+\alpha J^{*}(f(x, u, w))\right\}
$$

Proof: For all $x$ and $k$,

$$
J^{*}(x)-\frac{\alpha^{k} M}{1-\alpha} \leq\left(T^{k} J_{0}\right)(x) \leq J^{*}(x)+\frac{\alpha^{k} M}{1-\alpha}
$$

where $J_{0}(x) \equiv 0$ and $M \geq|g(x, u, w)|$. Applying $T$ to this relation, and using Monotonicity and Constant Shift,

$$
\begin{aligned}
\left(T J^{*}\right)(x)-\frac{\alpha^{k+1} M}{1-\alpha} & \leq\left(T^{k+1} J_{0}\right)(x) \\
& \leq\left(T J^{*}\right)(x)+\frac{\alpha^{k+1} M}{1-\alpha}
\end{aligned}
$$

Taking the limit as $k \rightarrow \infty$ and using the fact

$$
\lim _{k \rightarrow \infty}\left(T^{k+1} J_{0}\right)(x)=J^{*}(x)
$$

we obtain $J^{*}=T J^{*}$. Q.E.D.

## THE CONTRACTION PROPERTY

- Contraction property: For any bounded functions $J$ and $J^{\prime}$, and any $\mu$,

$$
\max _{x}\left|(T J)(x)-\left(T J^{\prime}\right)(x)\right| \leq \alpha \max _{x}\left|J(x)-J^{\prime}(x)\right|,
$$

$\max _{x}\left|\left(T_{\mu} J\right)(x)-\left(T_{\mu} J^{\prime}\right)(x)\right| \leq \alpha \max _{x}\left|J(x)-J^{\prime}(x)\right|$.
Proof: Denote $c=\max _{x \in S}\left|J(x)-J^{\prime}(x)\right|$. Then

$$
J(x)-c \leq J^{\prime}(x) \leq J(x)+c, \quad \forall x
$$

Apply $T$ to both sides, and use the Monotonicity and Constant Shift properties:

$$
(T J)(x)-\alpha c \leq\left(T J^{\prime}\right)(x) \leq(T J)(x)+\alpha c, \quad \forall x
$$

Hence

$$
\left|(T J)(x)-\left(T J^{\prime}\right)(x)\right| \leq \alpha c, \quad \forall x .
$$

Q.E.D.

- Note: This implies that $J^{*}$ is the unique solution of $J^{*}=T J^{*}$, and $J_{\mu}$ is the unique solution of $J_{\mu}=T_{\mu} J_{\mu}$

# NEC. AND SUFFICIENT OPT. CONDITION 

- A stationary policy $\mu$ is optimal if and only if $\mu(x)$ attains the minimum in Bellman's equation for each $x$; i.e.,

$$
T J^{*}=T_{\mu} J^{*}
$$

or, equivalently, for all $x$,
$\mu(x) \in \arg \min _{u \in U(x)} \underset{w}{E}\left\{g(x, u, w)+\alpha J^{*}(f(x, u, w))\right\}$
Proof: If $T J^{*}=T_{\mu} J^{*}$, then using Bellman's equation ( $J^{*}=T J^{*}$ ), we have

$$
J^{*}=T_{\mu} J^{*}
$$

so by uniqueness of the fixed point of $T_{\mu}$, we obtain $J^{*}=J_{\mu}$; i.e., $\mu$ is optimal.

- Conversely, if the stationary policy $\mu$ is optimal, we have $J^{*}=J_{\mu}$, so

$$
J^{*}=T_{\mu} J^{*} .
$$

Combining this with Bellman's Eq. $\left(J^{*}=T J^{*}\right)$, we obtain $T J^{*}=T_{\mu} J^{*}$. Q.E.D.

# APPROXIMATE DYNAMIC PROGRAMMING 

## LECTURE 2

## LECTURE OUTLINE

- Review of discounted problem theory
- Review of shorthand notation
- Algorithms for discounted DP
- Value iteration
- Various forms of policy iteration
- Optimistic policy iteration
- Q-factors and Q-learning
- Other DP models - Continuous space and time
- A more abstract view of DP
- Asynchronous algorithms

## DISCOUNTED PROBLEMS/BOUNDED COST

- Stationary system with arbitrary state space

$$
x_{k+1}=f\left(x_{k}, u_{k}, w_{k}\right), \quad k=0,1, \ldots
$$

- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$
$J_{\pi}\left(x_{0}\right)=\lim _{N \rightarrow \infty} \underset{\substack{w_{k} \\ k=0,1, \ldots}}{E}\left\{\sum_{k=0}^{N-1} \alpha^{k} g\left(x_{k}, \mu_{k}\left(x_{k}\right), w_{k}\right)\right\}$
with $\alpha<1$, and for some $M$, we have $|g(x, u, w)| \leq$ $M$ for all $(x, u, w)$
- Shorthand notation for DP mappings (operate on functions of state to produce other functions)
$(T J)(x)=\min _{u \in U(x)} \underset{w}{E}\{g(x, u, w)+\alpha J(f(x, u, w))\}, \forall x$
$T J$ is the optimal cost function for the one-stage problem with stage cost $g$ and terminal cost $\alpha J$.
- For any stationary policy $\mu$

$$
\left(T_{\mu} J\right)(x)=\underset{w}{E}\{g(x, \mu(x), w)+\alpha J(f(x, \mu(x), w))\}, \forall x
$$

## "SHORTHAND" THEORY - A SUMMARY

- Bellman's equation: $J^{*}=T J^{*}, J_{\mu}=T_{\mu} J_{\mu}$ or

$$
\begin{aligned}
J^{*}(x) & =\min _{u \in U(x)} \underset{w}{E}\left\{g(x, u, w)+\alpha J^{*}(f(x, u, w))\right\}, \forall x \\
J_{\mu}(x) & =\underset{w}{E}\left\{g(x, \mu(x), w)+\alpha J_{\mu}(f(x, \mu(x), w))\right\}, \forall x
\end{aligned}
$$

- Optimality condition:
$\mu:$ optimal $<==>\quad T_{\mu} J^{*}=T J^{*}$
i.e.,
$\mu(x) \in \arg \min _{u \in U(x)} \underset{w}{E}\left\{g(x, u, w)+\alpha J^{*}(f(x, u, w))\right\}, \forall x$
- Value iteration: For any (bounded) $J$

$$
J^{*}(x)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(x), \quad \forall x
$$

- Policy iteration: Given $\mu^{k}$,
- Find $J_{\mu^{k}}$ from $J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}}$ (policy evaluation); then
- Find $\mu^{k+1}$ such that $T_{\mu^{k+1}} J_{\mu^{k}}=T J_{\mu^{k}}$ (policy improvement)

## MAJOR PROPERTIES

- Monotonicity property: For any functions $J$ and $J^{\prime}$ on the state space $X$ such that $J(x) \leq J^{\prime}(x)$ for all $x \in X$, and any $\mu$

$$
(T J)(x) \leq\left(T J^{\prime}\right)(x), \quad\left(T_{\mu} J\right)(x) \leq\left(T_{\mu} J^{\prime}\right)(x), \quad \forall x \in X
$$

- Contraction property: For any bounded functions $J$ and $J^{\prime}$, and any $\mu$,

$$
\max _{x}\left|(T J)(x)-\left(T J^{\prime}\right)(x)\right| \leq \alpha \max _{x}\left|J(x)-J^{\prime}(x)\right|,
$$

$$
\max _{x}\left|\left(T_{\mu} J\right)(x)-\left(T_{\mu} J^{\prime}\right)(x)\right| \leq \alpha \max _{x}\left|J(x)-J^{\prime}(x)\right|
$$

- Compact Contraction Notation:

$$
\left\|T J-T J^{\prime}\right\| \leq \alpha\left\|J-J^{\prime}\right\|, \quad\left\|T_{\mu} J-T_{\mu} J^{\prime}\right\| \leq \alpha\left\|J-J^{\prime}\right\|,
$$

where for any bounded function $J$, we denote by $\|J\|$ the sup-norm

$$
\|J\|=\max _{x}|J(x)|
$$

## THE TWO MAIN ALGORITHMS: VI AND PI

- Value iteration: For any (bounded) $J$

$$
J^{*}(x)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(x), \quad \forall x
$$

- Policy iteration: Given $\mu^{k}$
- Policy evaluation: Find $J_{\mu^{k}}$ by solving

$$
\begin{aligned}
& J_{\mu^{k}}(x)=\underset{w}{E}\left\{g\left(x, \mu^{k}(x), w\right)+\alpha J_{\mu^{k}}\left(f\left(x, \mu^{k}(x), w\right)\right)\right\}, \forall x \\
& \quad \text { or } J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}}
\end{aligned}
$$

- Policy improvement: Let $\mu^{k+1}$ be such that

$$
\mu^{k+1}(x) \in \arg \min _{u \in U(x)} \underset{w}{E}\left\{g(x, u, w)+\alpha J_{\mu^{k}}(f(x, u, w))\right\}, \forall x
$$

$$
\text { or } T_{\mu^{k+1}} J_{\mu^{k}}=T J_{\mu^{k}}
$$

- For the case of $n$ states, policy evaluation is equivalent to solving an $n \times n$ linear system of equations: $J_{\mu}=g_{\mu}+\alpha P_{\mu} J_{\mu}$
- For large $n$, exact PI is out of the question (even though it terminates finitely as we will show)

## JUSTIFICATION OF POLICY ITERATION

- We can show that $J_{\mu^{k}} \geq J_{\mu^{k+1}}$ for all $k$
- Proof: For given $k$, we have

$$
J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}} \geq T J_{\mu^{k}}=T_{\mu^{k+1}} J_{\mu^{k}}
$$

Using the monotonicity property of DP,

$$
J_{\mu^{k}} \geq T_{\mu^{k+1}} J_{\mu^{k}} \geq T_{\mu^{k+1}}^{2} J_{\mu^{k}} \geq \cdots \geq \lim _{N \rightarrow \infty} T_{\mu^{k+1}}^{N} J_{\mu^{k}}
$$

- Since

$$
\lim _{N \rightarrow \infty} T_{\mu^{k+1}}^{N} J_{\mu^{k}}=J_{\mu^{k+1}}
$$

we have $J_{\mu^{k}} \geq J_{\mu^{k+1}}$.

- If $J_{\mu^{k}}=J_{\mu^{k+1}}$, all above inequalities hold as equations, so $J_{\mu^{k}}$ solves Bellman's equation. Hence $J_{\mu^{k}}=J^{*}$
- Thus at iteration $k$ either the algorithm generates a strictly improved policy or it finds an optimal policy
- For a finite spaces MDP, the algorithm terminates with an optimal policy
- For infinite spaces MDP, convergence (in an infinite number of iterations) can be shown

## OPTIMISTIC POLICY ITERATION

- Optimistic PI: This is PI, where policy evaluation is done approximately, with a finite number of VI
- So we approximate the policy evaluation

$$
J_{\mu} \approx T_{\mu}^{m} J
$$

for some number $m \in[1, \infty)$ and initial $J$

- Shorthand definition: For some integers $m_{k}$

$$
T_{\mu^{k}} J_{k}=T J_{k}, \quad J_{k+1}=T_{\mu^{k}}^{m_{k}} J_{k}, \quad k=0,1, \ldots
$$

- If $m_{k} \equiv 1$ it becomes VI
- If $m_{k}=\infty$ it becomes PI
- Converges for both finite and infinite spaces discounted problems (in an infinite number of iterations)
- Typically works faster than VI and PI (for large problems)

## APPROXIMATE PI

- Suppose that the policy evaluation is approximate,

$$
\left\|J_{k}-J_{\mu^{k}}\right\| \leq \delta, \quad k=0,1, \ldots
$$

and policy improvement is approximate,

$$
\left\|T_{\mu^{k+1}} J_{k}-T J_{k}\right\| \leq \epsilon, \quad k=0,1, \ldots
$$

where $\delta$ and $\epsilon$ are some positive scalars.

- Error Bound I: The sequence $\left\{\mu^{k}\right\}$ generated by approximate policy iteration satisfies

$$
\limsup _{k \rightarrow \infty}\left\|J_{\mu^{k}}-J^{*}\right\| \leq \frac{\epsilon+2 \alpha \delta}{(1-\alpha)^{2}}
$$

- Typical practical behavior: The method makes steady progress up to a point and then the iterates $J_{\mu^{k}}$ oscillate within a neighborhood of $J^{*}$.
- Error Bound II: If in addition the sequence $\left\{\mu^{k}\right\}$ "terminates" at $\bar{\mu}$ (i.e., keeps generating $\bar{\mu}$ )

$$
\left\|J_{\bar{\mu}}-J^{*}\right\| \leq \frac{\epsilon+2 \alpha \delta}{1-\alpha}
$$

## Q-FACTORS I

- Optimal Q-factor of $(x, u)$ :

$$
Q^{*}(x, u)=E\left\{g(x, u, w)+\alpha J^{*}(\bar{x})\right\}
$$

with $\bar{x}=f(x, u, w)$. It is the cost of starting at $x$, applying $u$ is the 1st stage, and an optimal policy after the 1st stage

- We can write Bellman's equation as

$$
J^{*}(x)=\min _{u \in U(x)} Q^{*}(x, u), \quad \forall x
$$

- We can equivalently write the VI method as

$$
J_{k+1}(x)=\min _{u \in U(x)} Q_{k+1}(x, u), \quad \forall x
$$

where $Q_{k+1}$ is generated by

$$
Q_{k+1}(x, u)=E\left\{g(x, u, w)+\alpha \min _{v \in U(\bar{x})} Q_{k}(\bar{x}, v)\right\}
$$

with $\bar{x}=f(x, u, w)$

## Q-FACTORS II

- Q-factors are costs in an "augmented" problem where states are $(x, u)$
- They satisfy a Bellman equation $Q^{*}=F Q^{*}$ where

$$
(F Q)(x, u)=E\left\{g(x, u, w)+\alpha \min _{v \in U(\bar{x})} Q(\bar{x}, v)\right\}
$$

where $\bar{x}=f(x, u, w)$

- VI and PI for Q -factors are mathematically equivalent to VI and PI for costs
- They require equal amount of computation ... they just need more storage
- Having optimal Q-factors is convenient when implementing an optimal policy on-line by

$$
\mu^{*}(x)=\min _{u \in U(x)} Q^{*}(x, u)
$$

- Once $Q^{*}(x, u)$ are known, the model $[g$ and $E\{\cdot\}]$ is not needed. Model-free operation
- Q-Learning (to be discussed later) is a sampling method that calculates $Q^{*}(x, u)$ using a simulator of the system (no model needed)

## OTHER DP MODELS

- We have looked so far at the (discrete or continuous spaces) discounted models for which the analysis is simplest and results are most powerful
- Other DP models include:
- Undiscounted problems $(\alpha=1)$ : They may include a special termination state (stochastic shortest path problems)
- Continuous-time finite-state MDP: The time between transitions is random and state-and-control-dependent (typical in queueing systems, called Semi-Markov MDP). These can be viewed as discounted problems with state-and-control-dependent discount factors
- Continuous-time, continuous-space models: Classical automatic control, process control, robotics
- Substantial differences from discrete-time
- Mathematically more complex theory (particularly for stochastic problems)
- Deterministic versions can be analyzed using classical optimal control theory
- Admit treatment by DP, based on time discretization

## CONTINUOUS-TIME MODELS

- System equation: $d x(t) / d t=f(x(t), u(t))$
- Cost function: $\int_{0}^{\infty} g(x(t), u(t))$
- Optimal cost starting from $x: J^{*}(x)$
- $\delta$-Discretization of time: $x_{k+1}=x_{k}+\delta \cdot f\left(x_{k}, u_{k}\right)$
- Bellman equation for the $\delta$-discretized problem:

$$
J_{\delta}^{*}(x)=\min _{u}\left\{\delta \cdot g(x, u)+J_{\delta}^{*}(x+\delta \cdot f(x, u))\right\}
$$

- Take $\delta \rightarrow 0$, to obtain the Hamilton-JacobiBellman equation [assuming $\lim _{\delta \rightarrow 0} J_{\delta}^{*}(x)=J^{*}(x)$ ]

$$
0=\min _{u}\left\{g(x, u)+\nabla J^{*}(x)^{\prime} f(x, u)\right\}, \quad \forall x
$$

- Policy Iteration (informally):
- Policy evaluation: Given current $\mu$, solve

$$
0=g(x, \mu(x))+\nabla J_{\mu}(x)^{\prime} f(x, \mu(x)), \quad \forall x
$$

- Policy improvement: Find

$$
\begin{aligned}
& \bar{\mu}(x) \in \arg \min _{u}\left\{g(x, u)+\nabla J_{\mu}(x)^{\prime} f(x, u\right. \\
& \text { ote: Need to learn } \nabla J_{\mu}(x) \text { NOT } J_{\mu}(x)
\end{aligned}
$$

## A MORE GENERAL/ABSTRACT VIEW OF DP

- Let $Y$ be a real vector space with a norm $\|\cdot\|$ - A function $F: Y \mapsto Y$ is said to be a contraction mapping if for some $\rho \in(0,1)$, we have

$$
\|F y-F z\| \leq \rho\|y-z\|, \quad \text { for all } y, z \in Y .
$$

$\rho$ is called the modulus of contraction of $F$.

- Important example: Let $X$ be a set (e.g., state space in DP), $v: X \mapsto \Re$ be a positive-valued function. Let $B(X)$ be the set of all functions $J: X \mapsto \Re$ such that $J(x) / v(x)$ is bounded over $x$.
- We define a norm on $B(X)$, called the weighted sup-norm, by

$$
\|J\|=\max _{x \in X} \frac{|J(x)|}{v(x)} .
$$

- Important special case: The discounted problem mappings $T$ and $T_{\mu}[$ for $v(x) \equiv 1, \rho=\alpha]$.

## CONTRACTION MAPPINGS: AN EXAMPLE

- Consider extension from finite to countable state space, $X=\{1,2, \ldots\}$, and a weighted sup norm with respect to which the one stage costs are bounded
- Suppose that $T_{\mu}$ has the form

$$
\left(T_{\mu} J\right)(i)=b_{i}+\alpha \sum_{j \in X} a_{i j} J(j), \quad \forall i=1,2, \ldots
$$

where $b_{i}$ and $a_{i j}$ are some scalars. Then $T_{\mu}$ is a contraction with modulus $\rho$ if and only if

$$
\frac{\sum_{j \in X}\left|a_{i j}\right| v(j)}{v(i)} \leq \rho, \quad \forall i=1,2, \ldots
$$

- Consider $T$,

$$
(T J)(i)=\min _{\mu}\left(T_{\mu} J\right)(i), \quad \forall i=1,2, \ldots
$$

where for each $\mu \in M, T_{\mu}$ is a contraction mapping with modulus $\rho$. Then $T$ is a contraction mapping with modulus $\rho$

- Allows extensions of main DP results from bounded one-stage cost to interesting unbounded one-stage cost cases.

## CONTRACTION MAPPING FIXED-POINT TH.

- Contraction Mapping Fixed-Point Theorem: If $F: B(X) \mapsto B(X)$ is a contraction with modulus $\rho \in(0,1)$, then there exists a unique $J^{*} \in B(X)$ such that

$$
J^{*}=F J^{*} .
$$

Furthermore, if $J$ is any function in $B(X)$, then $\left\{F^{k} J\right\}$ converges to $J^{*}$ and we have

$$
\left\|F^{k} J-J^{*}\right\| \leq \rho^{k}\left\|J-J^{*}\right\|, \quad k=1,2, \ldots
$$

- This is a special case of a general result for contraction mappings $F: Y \mapsto Y$ over normed vector spaces $Y$ that are complete: every sequence $\left\{y_{k}\right\}$ that is Cauchy (satisfies $\left\|y_{m}-y_{n}\right\| \rightarrow 0$ as $m, n \rightarrow \infty)$ converges.
- The space $B(X)$ is complete (see the text for a proof).

## ABSTRACT FORMS OF DP

- We consider an abstract form of DP based on monotonicity and contraction
- Abstract Mapping: Denote $R(X)$ : set of realvalued functions $J: X \mapsto \Re$, and let $H: X \times U \times$ $R(X) \mapsto \Re$ be a given mapping. We consider the mapping

$$
(T J)(x)=\min _{u \in U(x)} H(x, u, J), \quad \forall x \in X .
$$

- We assume that $(T J)(x)>-\infty$ for all $x \in X$, so $T$ maps $R(X)$ into $R(X)$.
- Abstract Policies: Let $\mathcal{M}$ be the set of "policies", i.e., functions $\mu$ such that $\mu(x) \in U(x)$ for all $x \in X$.
- For each $\mu \in \mathcal{M}$, we consider the mapping $T_{\mu}: R(X) \mapsto R(X)$ defined by

$$
\left(T_{\mu} J\right)(x)=H(x, \mu(x), J), \quad \forall x \in X
$$

- Find a function $J^{*} \in R(X)$ such that

$$
J^{*}(x)=\min _{u \in U(x)} H\left(x, u, J^{*}\right), \quad \forall x \in X
$$

## EXAMPLES

- Discounted problems

$$
H(x, u, J)=E\{g(x, u, w)+\alpha J(f(x, u, w))\}
$$

- Discounted "discrete-state continuous-time" Semi-Markov Problems (e.g., queueing)

$$
H(x, u, J)=G(x, u)+\sum_{y=1}^{n} m_{x y}(u) J(y)
$$

where $m_{x y}$ are "discounted" transition probabilities, defined by the distribution of transition times

- Minimax Problems/Games

$$
H(x, u, J)=\max _{w \in W(x, u)}[g(x, u, w)+\alpha J(f(x, u, w))]
$$

- Shortest Path Problems

$$
H(x, u, J)= \begin{cases}a_{x u}+J(u) & \text { if } u \neq d \\ a_{x d} & \text { if } u=d\end{cases}
$$

where $d$ is the destination. There are stochastic and minimax versions of this problem

## ASSUMPTIONS

- Monotonicity: If $J, J^{\prime} \in R(X)$ and $J \leq J^{\prime}$,

$$
H(x, u, J) \leq H\left(x, u, J^{\prime}\right), \quad \forall x \in X, u \in U(x)
$$

- We can show all the standard analytical and computational results of discounted DP if monotonicity and the following assumption holds:
- Contraction:
- For every $J \in B(X)$, the functions $T_{\mu} J$ and $T J$ belong to $B(X)$
- For some $\alpha \in(0,1)$, and all $\mu$ and $J, J^{\prime} \in$ $B(X)$, we have

$$
\left\|T_{\mu} J-T_{\mu} J^{\prime}\right\| \leq \alpha\left\|J-J^{\prime}\right\|
$$

- With just monotonicity assumption (as in undiscounted problems) we can still show various forms of the basic results under appropriate conditions
- A weaker substitute for contraction assumption is semicontractiveness: (roughly) for some $\mu, T_{\mu}$ is a contraction and for others it is not; also the "noncontractive" $\mu$ are not optimal

## RESULTS USING CONTRACTION

- Proposition 1: The mappings $T_{\mu}$ and $T$ are weighted sup-norm contraction mappings with modulus $\alpha$ over $B(X)$, and have unique fixed points in $B(X)$, denoted $J_{\mu}$ and $J^{*}$, respectively (cf. Bellman's equation).

Proof: From the contraction property of $H$.

- Proposition 2: For any $J \in B(X)$ and $\mu \in \mathcal{M}$,

$$
\lim _{k \rightarrow \infty} T_{\mu}^{k} J=J_{\mu}, \quad \lim _{k \rightarrow \infty} T^{k} J=J^{*}
$$

(cf. convergence of value iteration).
Proof: From the contraction property of $T_{\mu}$ and $T$.

- Proposition 3: We have $T_{\mu} J^{*}=T J^{*}$ if and only if $J_{\mu}=J^{*}$ (cf. optimality condition).

Proof: $T_{\mu} J^{*}=T J^{*}$, then $T_{\mu} J^{*}=J^{*}$, implying $J^{*}=J_{\mu}$. Conversely, if $J_{\mu}=J^{*}$, then $T_{\mu} J^{*}=$ $T_{\mu} J_{\mu}=J_{\mu}=J^{*}=T J^{*}$.

RESULTS USING MON. AND CONTRACTION

- Optimality of fixed point:

$$
J^{*}(x)=\min _{\mu \in \mathcal{M}} J_{\mu}(x), \quad \forall x \in X
$$

- Existence of a nearly optimal policy: For every $\epsilon>0$, there exists $\mu_{\epsilon} \in \mathcal{M}$ such that

$$
J^{*}(x) \leq J_{\mu_{\epsilon}}(x) \leq J^{*}(x)+\epsilon, \quad \forall x \in X
$$

- Nonstationary policies: Consider the set $\Pi$ of all sequences $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$ with $\mu_{k} \in \mathcal{M}$ for all $k$, and define
$J_{\pi}(x)=\liminf _{k \rightarrow \infty}\left(T_{\mu_{0}} T_{\mu_{1}} \cdots T_{\mu_{k}} J\right)(x), \quad \forall x \in X$,
with $J$ being any function (the choice of $J$ does not matter)
- We have

$$
J^{*}(x)=\min _{\pi \in \Pi} J_{\pi}(x), \quad \forall x \in X
$$

# THE TWO MAIN ALGORITHMS: VI AND PI 

- Value iteration: For any (bounded) $J$

$$
J^{*}(x)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(x), \quad \forall x
$$

- Policy iteration: Given $\mu^{k}$
- Policy evaluation: Find $J_{\mu^{k}}$ by solving

$$
J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}}
$$

- Policy improvement: Find $\mu^{k+1}$ such that

$$
T_{\mu^{k+1}} J_{\mu^{k}}=T J_{\mu^{k}}
$$

- Optimistic PI: This is PI, where policy evaluation is carried out by a finite number of VI
- Shorthand definition: For some integers $m_{k}$

$$
\begin{aligned}
& T_{\mu^{k}} J_{k}=T J_{k}, \quad J_{k+1}=T_{\mu^{k}}^{m_{k}} J_{k}, \quad k=0,1, \ldots \\
- & \text { If } m_{k} \equiv 1 \text { it becomes VI } \\
- & \text { If } m_{k}=\infty \text { it becomes PI } \\
- & \text { For intermediate values of } m_{k}, \text { it is generally } \\
& \text { more efficient than either VI or PI }
\end{aligned}
$$

## ASYNCHRONOUS ALGORITHMS

- Motivation for asynchronous algorithms
- Faster convergence
- Parallel and distributed computation
- Simulation-based implementations
- General framework: Partition $X$ into disjoint nonempty subsets $X_{1}, \ldots, X_{m}$, and use separate processor $\ell$ updating $J(x)$ for $x \in X_{\ell}$
- Let $J$ be partitioned as

$$
J=\left(J_{1}, \ldots, J_{m}\right),
$$

where $J_{\ell}$ is the restriction of $J$ on the set $X_{\ell}$.

- Synchronous VI algorithm:

$$
J_{\ell}^{t+1}(x)=T\left(J_{1}^{t}, \ldots, J_{m}^{t}\right)(x), \quad x \in X_{\ell}, \ell=1, \ldots, m
$$

- Asynchronous VI algorithm: For some subsets of times $\mathcal{R}_{\ell}$,

$$
J_{\ell}^{t+1}(x)= \begin{cases}T\left(J_{1}^{\tau_{\ell 1}(t)}, \ldots, J_{m}^{\tau_{\ell m}(t)}\right)(x) & \text { if } t \in \mathcal{R}_{\ell} \\ J_{\ell}^{t}(x) & \text { if } t \notin \mathcal{R}_{\ell}\end{cases}
$$

where $t-\tau_{\ell j}(t)$ are communication "delays"

## ONE-STATE-AT-A-TIME ITERATIONS

- Important special case: Assume $n$ "states", a separate processor for each state, and no delays
- Generate a sequence of states $\left\{x^{0}, x^{1}, \ldots\right\}$, generated in some way, possibly by simulation (each state is generated infinitely often)
- Asynchronous VI:

$$
J_{\ell}^{t+1}= \begin{cases}T\left(J_{1}^{t}, \ldots, J_{n}^{t}\right)(\ell) & \text { if } \ell=x^{t}, \\ J_{\ell}^{t} & \text { if } \ell \neq x^{t},\end{cases}
$$

where $T\left(J_{1}^{t}, \ldots, J_{n}^{t}\right)(\ell)$ denotes the $\ell$-th component of the vector

$$
T\left(J_{1}^{t}, \ldots, J_{n}^{t}\right)=T J^{t}
$$

- The special case where

$$
\left\{x^{0}, x^{1}, \ldots\right\}=\{1, \ldots, n, 1, \ldots, n, 1, \ldots\}
$$

is the Gauss-Seidel method

## ASYNCHRONOUS CONV. THEOREM I

- KEY FACT: VI and also PI (with some modifications) still work when implemented asynchronously
- Assume that for all $\ell, j=1, \ldots, m, \mathcal{R}_{\ell}$ is infinite and $\lim _{t \rightarrow \infty} \tau_{\ell j}(t)=\infty$
- Proposition: Let $T$ have a unique fixed point $J^{*}$, and assume that there is a sequence of nonempty subsets $\{S(k)\} \subset R(X)$ with $S(k+1) \subset S(k)$ for all $k$, and with the following properties:
(1) Synchronous Convergence Condition: Every sequence $\left\{J^{k}\right\}$ with $J^{k} \in S(k)$ for each $k$, converges pointwise to $J^{*}$. Moreover,

$$
T J \in S(k+1), \quad \forall J \in S(k), k=0,1, \ldots
$$

(2) Box Condition: For all $k, S(k)$ is a Cartesian product of the form

$$
S(k)=S_{1}(k) \times \cdots \times S_{m}(k),
$$

where $S_{\ell}(k)$ is a set of real-valued functions on $X_{\ell}, \ell=1, \ldots, m$.
Then for every $J \in S(0)$, the sequence $\left\{J^{t}\right\}$ generated by the asynchronous algorithm converges pointwise to $J^{*}$.

## ASYNCHRONOUS CONV. THEOREM II

- Interpretation of assumptions:

A synchronous iteration from any $J$ in $S(k)$ moves into $S(k+1)$ (component-by-component)

- Convergence mechanism:

Key: "Independent" component-wise improvement. An asynchronous component iteration from any $J$ in $S(k)$ moves into the corresponding component portion of $S(k+1)$

# APPROXIMATE DYNAMIC PROGRAMMING 

## LECTURE 3

## LECTURE OUTLINE

- Review of discounted DP
- Introduction to approximate DP
- Approximation architectures
- Simulation-based approximate policy iteration
- Approximate policy evaluation
- Some general issues about approximation and simulation

## REVIEW

## DISCOUNTED PROBLEMS/BOUNDED COST

- Stationary system with arbitrary state space

$$
x_{k+1}=f\left(x_{k}, u_{k}, w_{k}\right), \quad k=0,1, \ldots
$$

- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$
$J_{\pi}\left(x_{0}\right)=\lim _{N \rightarrow \infty} \underset{\substack{w_{k} \\ k=0,1, \ldots}}{E}\left\{\sum_{k=0}^{N-1} \alpha^{k} g\left(x_{k}, \mu_{k}\left(x_{k}\right), w_{k}\right)\right\}$
with $\alpha<1$, and for some $M$, we have $|g(x, u, w)| \leq$ $M$ for all $(x, u, w)$
- Shorthand notation for DP mappings (operate on functions of state to produce other functions)
$(T J)(x)=\min _{u \in U(x)} \underset{w}{E}\{g(x, u, w)+\alpha J(f(x, u, w))\}, \forall x$
$T J$ is the optimal cost function for the one-stage problem with stage cost $g$ and terminal cost $\alpha J$
- For any stationary policy $\mu$

$$
\left(T_{\mu} J\right)(x)=\underset{w}{E}\{g(x, \mu(x), w)+\alpha J(f(x, \mu(x), w))\}, \forall x
$$

## MDP - TRANSITION PROBABILITY NOTATION

- We will mostly assume the system is an $n$-state (controlled) Markov chain
- We will often switch to Markov chain notation
- States $i=1, \ldots, n($ instead of $x)$
- Transition probabilities $p_{i_{k} i_{k+1}}\left(u_{k}\right)$ [instead of $\left.x_{k+1}=f\left(x_{k}, u_{k}, w_{k}\right)\right]$
- Stage cost $g\left(i_{k}, u_{k}, i_{k+1}\right)$ [instead of $\left.g\left(x_{k}, u_{k}, w_{k}\right)\right]$
- Cost functions $J=(J(1), \ldots, J(n))$ (vectors in $\Re^{n}$ )
- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$
- Shorthand notation for DP mappings

$$
\begin{aligned}
& (T J)(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha J(j)), \quad i=1, \ldots, n, \\
& \left(T_{\mu} J\right)(i)=\sum_{j=1}^{n} p_{i j}(\mu(i))(g(i, \mu(i), j)+\alpha J(j)), \quad i=1, \ldots, n
\end{aligned}
$$

## "SHORTHAND" THEORY - A SUMMARY

- Bellman's equation: $J^{*}=T J^{*}, J_{\mu}=T_{\mu} J_{\mu}$ or

$$
J^{*}(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J^{*}(j)\right), \quad \forall i
$$

$$
J_{\mu}(i)=\sum_{j=1}^{n} p_{i j}(\mu(i))\left(g(i, \mu(i), j)+\alpha J_{\mu}(j)\right), \quad \forall i
$$

- Optimality condition:
$\mu:$ optimal $<==>\quad T_{\mu} J^{*}=T J^{*}$
i.e.,
$\mu(i) \in \arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J^{*}(j)\right), \quad \forall i$

# THE TWO MAIN ALGORITHMS: VI AND PI 

- Value iteration: For any $J \in \Re^{n}$

$$
J^{*}(i)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(i), \quad \forall i=1, \ldots, n
$$

- Policy iteration: Given $\mu^{k}$
- Policy evaluation: Find $J_{\mu^{k}}$ by solving

$$
\begin{aligned}
J_{\mu^{k}}(i) & =\sum_{j=1}^{n} p_{i j}\left(\mu^{k}(i)\right)\left(g\left(i, \mu^{k}(i), j\right)+\alpha J_{\mu^{k}}(j)\right), \quad i=1, \ldots, n \\
& \text { or } J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}} \\
- & \text { Policy improvement: Let } \mu^{k+1} \text { be such that }
\end{aligned}
$$

$$
\begin{aligned}
& \mu^{k+1}(i) \in \arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J_{\mu^{k}}(j)\right), \quad \forall i \\
& \quad \text { or } T_{\mu^{k+1}} J_{\mu^{k}}=T J_{\mu^{k}}
\end{aligned}
$$

- Policy evaluation is equivalent to solving an $n \times n$ linear system of equations
- For large $n$, exact PI is out of the question. We use instead optimistic PI (policy evaluation with a few VIs)

## APPROXIMATE DP

## GENERAL ORIENTATION TO ADP

- ADP (late 80s - present) is a breakthrough methodology that allows the application of DP to problems with many or infinite number of states.
- Other names for ADP are:
- "reinforcement learning" (RL).
- "neuro-dynamic programming" (NDP).
- "adaptive dynamic programming" (ADP).
- We will mainly adopt an $n$-state discounted model (the easiest case - but think of HUGE $n$ ).
- Extensions to other DP models (continuous space, continuous-time, not discounted) are possible (but more quirky). We will set aside for later.
- There are many approaches:
- Problem approximation
- Simulation-based approaches (we will focus on these)
- Simulation-based methods are of three types:
- Rollout (we will not discuss further)
- Approximation in value space
- Approximation in policy space

## WHY DO WE USE SIMULATION?

- One reason: Computational complexity advantage in computing sums/expectations involving a very large number of terms
- Any sum

$$
\sum_{i=1}^{n} a_{i}
$$

can be written as an expected value:

$$
\sum_{i=1}^{n} a_{i}=\sum_{i=1}^{n} \xi_{i} \frac{a_{i}}{\xi_{i}}=E_{\xi}\left\{\frac{a_{i}}{\xi_{i}}\right\},
$$

where $\xi$ is any prob. distribution over $\{1, \ldots, n\}$

- It can be approximated by generating many samples $\left\{i_{1}, \ldots, i_{k}\right\}$ from $\{1, \ldots, n\}$, according to distribution $\xi$, and Monte Carlo averaging:

$$
\sum_{i=1}^{n} a_{i}=E_{\xi}\left\{\frac{a_{i}}{\xi_{i}}\right\} \approx \frac{1}{k} \sum_{t=1}^{k} \frac{a_{i_{t}}}{\xi_{i_{t}}}
$$

- Simulation is also convenient when an analytical model of the system is unavailable, but a simulation/computer model is possible.

## APPROXIMATION IN VALUE AND <br> POLICY SPACE

## APPROXIMATION IN VALUE SPACE

- Approximate $J^{*}$ or $J_{\mu}$ from a parametric class $\tilde{J}(i ; r)$ where $i$ is the current state and $r=\left(r_{1}, \ldots, r_{m}\right)$ is a vector of "tunable" scalars weights
- Use $\tilde{J}$ in place of $J^{*}$ or $J_{\mu}$ in various algorithms and computations
- Role of $r$ : By adjusting $r$ we can change the "shape" of $\tilde{J}$ so that it is "close" to $J^{*}$ or $J_{\mu}$
- Two key issues:
- The choice of parametric class $\tilde{J}(i ; r) \quad$ (the approximation architecture)
- Method for tuning the weights ("training" the architecture)
- Success depends strongly on how these issues are handled ... also on insight about the problem
- A simulator may be used, particularly when there is no mathematical model of the system (but there is a computer model)
- We will focus on simulation, but this is not the only possibility
- We may also use parametric approximation for $Q$-factors or cost function differences

## APPROXIMATION ARCHITECTURES

- Divided in linear and nonlinear [i.e., linear or nonlinear dependence of $\tilde{J}(i ; r)$ on $r$ ]
- Linear architectures are easier to train, but nonlinear ones (e.g., neural networks) are richer
- Computer chess example:
- Think of board position as state and move as control
- Uses a feature-based position evaluator that assigns a score (or approximate $Q$-factor) to each position/move

- Relatively few special features and weights, and multistep lookahead

## LINEAR APPROXIMATION ARCHITECTURES

- Often, the features encode much of the nonlinearity inherent in the cost function approximated - Then the approximation may be quite accurate without a complicated architecture (as an extreme example, the ideal feature is the true cost function)
- With well-chosen features, we can use a linear architecture: $\tilde{J}(i ; r)=\phi(i)^{\prime} r, i=1, \ldots, n$, or

$$
\tilde{J}(r)=\Phi r=\sum_{j=1}^{s} \Phi_{j} r_{j}
$$

$\Phi$ : the matrix whose rows are $\phi(i)^{\prime}, i=1, \ldots, n$, $\Phi_{j}$ is the $j$ th column of $\Phi$

- This is approximation on the subspace

$$
S=\left\{\Phi r \mid r \in \Re^{s}\right\}
$$

spanned by the columns of $\Phi$ (basis functions)

- Many examples of feature types: Polynomial approximation, radial basis functions, etc

## ILLUSTRATIONS: POLYNOMIAL TYPE

- Polynomial Approximation, e.g., a quadratic approximating function. Let the state be $i=$ $\left(i_{1}, \ldots, i_{q}\right)$ (i.e., have $q$ "dimensions") and define $\phi_{0}(i)=1, \quad \phi_{k}(i)=i_{k}, \quad \phi_{k m}(i)=i_{k} i_{m}, \quad k, m=1, \ldots, q$ Linear approximation architecture:

$$
\tilde{J}(i ; r)=r_{0}+\sum_{k=1}^{q} r_{k} i_{k}+\sum_{k=1}^{q} \sum_{m=k}^{q} r_{k m} i_{k} i_{m},
$$

where $r$ has components $r_{0}, r_{k}$, and $r_{k m}$.

- Interpolation: A subset $I$ of special/representative states is selected, and the parameter vector $r$ has one component $r_{i}$ per state $i \in I$. The approximating function is

$$
\tilde{J}(i ; r)=r_{i}, \quad i \in I,
$$

$\tilde{J}(i ; r)=$ interpolation using the values at $i \in I, i \notin I$
For example, piecewise constant, piecewise linear, more general polynomial interpolations.

## A DOMAIN SPECIFIC EXAMPLE

- Tetris game (used as testbed in competitions)

......

## TERMINATION

- $J^{*}(i)$ : optimal score starting from position $i$ - Number of states $>2^{200}$ (for $10 \times 20$ board)
- Success with just 22 features, readily recognized by tetris players as capturing important aspects of the board position (heights of columns, etc)

## APPROX. PI - OPTION TO APPROX. $J_{\mu}$ OR $Q_{\mu}$

- Use simulation to approximate the cost $J_{\mu}$ of the current policy $\mu$
- Generate "improved" policy $\bar{\mu}$ by minimizing in (approx.) Bellman equation

Approximate Policy Evaluation

Policy Improvement

- Altenatively approximate the $Q$-factors of $\mu$

Approximate Policy Evaluation

## APPROXIMATING $J^{*}$ OR $Q^{*}$

- Approximation of the optimal cost function $J^{*}$
- $Q$-Learning: Use a simulation algorithm to approximate the $Q$-factors

$$
Q^{*}(i, u)=g(i, u)+\alpha \sum_{j=1}^{n} p_{i j}(u) J^{*}(j) ;
$$

and the optimal costs

$$
J^{*}(i)=\min _{u \in U(i)} Q^{*}(i, u)
$$

- Bellman Error approach: Find $r$ to

$$
\min _{r} E_{i}\left\{(\tilde{J}(i ; r)-(T \tilde{J})(i ; r))^{2}\right\}
$$

where $E_{i}\{\cdot\}$ is taken with respect to some distribution over the states

- Approximate Linear Programming (we will not discuss here)
- $Q$-learning can also be used with approximations
- $Q$-learning and Bellman error approach can also be used for policy evaluation

## APPROXIMATION IN POLICY SPACE

- A brief discussion; we will return to it later.
- Use parametrization $\mu(i ; r)$ of policies with a vector $r=\left(r_{1}, \ldots, r_{s}\right)$. Examples:
- Polynomial, e.g., $\mu(i ; r)=r_{1}+r_{2} \cdot i+r_{3} \cdot i^{2}$
- Linear feature-based

$$
\mu(i ; r)=\phi_{1}(i) \cdot r_{1}+\phi_{2}(i) \cdot r_{2}
$$

- Optimize the cost over $r$. For example:
- Each value of $r$ defines a stationary policy, with cost starting at state $i$ denoted by $\tilde{J}(i ; r)$.
- Let $\left(p_{1}, \ldots, p_{n}\right)$ be some probability distribution over the states, and minimize over $r$

$$
\sum_{i=1}^{n} p_{i} \tilde{J}(i ; r)
$$

- Use a random search, gradient, or other method - A special case: The parameterization of the policies is indirect, through a cost approximation architecture $\hat{J}$, i.e.,
$\mu(i ; r) \in \arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha \hat{J}(j ; r))$

## APPROXIMATE POLICY EVALUATION METHODS

## DIRECT POLICY EVALUATION

- Approximate the cost of the current policy by using least squares and simulation-generated cost samples
- Amounts to projection of $J_{\mu}$ onto the approximation subspace

Direct Method: Projection of cost vector $J_{\mu}$

- Solution by least squares methods
- Regular and optimistic policy iteration
- Nonlinear approximation architectures may also be used

## DIRECT EVALUATION BY SIMULATION

- Projection by Monte Carlo Simulation: Compute the projection $\Pi J_{\mu}$ of $J_{\mu}$ on subspace $S=$ $\left\{\Phi r \mid r \in \Re^{s}\right\}$, with respect to a weighted Euclidean norm $\|\cdot\|_{\xi}$
- Equivalently, find $\Phi r^{*}$, where

$$
r^{*}=\arg \min _{r \in \Re^{s}}\left\|\Phi r-J_{\mu}\right\|_{\xi}^{2}=\arg \min _{r \in \Re^{s}} \sum_{i=1}^{n} \xi_{i}\left(\phi(i)^{\prime} r-J_{\mu}(i)\right)^{2}
$$

- Setting to 0 the gradient at $r^{*}$,

$$
r^{*}=\left(\sum_{i=1}^{n} \xi_{i} \phi(i) \phi(i)^{\prime}\right)^{-1} \sum_{i=1}^{n} \xi_{i} \phi(i) J_{\mu}(i)
$$

- Generate samples $\left\{\left(i_{1}, J_{\mu}\left(i_{1}\right)\right), \ldots,\left(i_{k}, J_{\mu}\left(i_{k}\right)\right)\right\}$ using distribution $\xi$
- Approximate by Monte Carlo the two "expected values" with low-dimensional calculations

$$
\hat{r}_{k}=\left(\sum_{t=1}^{k} \phi\left(i_{t}\right) \phi\left(i_{t}\right)^{\prime}\right)^{-1} \sum_{t=1}^{k} \phi\left(i_{t}\right) J_{\mu}\left(i_{t}\right)
$$

- Equivalent least squares alternative calculation:

$$
\hat{r}_{k}=\arg \min _{r \in \Re^{s}} \sum_{t=1}^{k}\left(\phi\left(i_{t}\right)^{\prime} r-J_{\mu}\left(i_{t}\right)\right)^{2}
$$

## INDIRECT POLICY EVALUATION

- An example: Galerkin approximation
- Solve the projected equation $\Phi r=\Pi T_{\mu}(\Phi r)$ where $\Pi$ is projection w/ respect to a suitable weighted Euclidean norm

Direct Method: Projection of cost vector $J_{\mu}$

Indirect Method: Solving a projected form of Bellman's equation

- Solution methods that use simulation (to manage the calculation of $\Pi$ )
$-\mathrm{TD}(\lambda)$ : Stochastic iterative algorithm for solving $\Phi r=\Pi T_{\mu}(\Phi r)$
- LSTD $(\lambda)$ : Solves a simulation-based approximation w/ a standard solver
$-\operatorname{LSPE}(\lambda)$ : A simulation-based form of projected value iteration; essentially

$$
\Phi r_{k+1}=\Pi T_{\mu}\left(\Phi r_{k}\right)+\text { simulation noise }
$$

## BELLMAN EQUATION ERROR METHODS

- Another example of indirect approximate policy evaluation:

$$
\begin{equation*}
\min _{r}\left\|\Phi r-T_{\mu}(\Phi r)\right\|_{\xi}^{2} \tag{*}
\end{equation*}
$$

where $\|\cdot\|_{\xi}$ is Euclidean norm, weighted with respect to some distribution $\xi$

- It is closely related to the projected equation/Galerkin approach (with a special choice of projection norm)
- Several ways to implement projected equation and Bellman error methods by simulation. They involve:
- Generating many random samples of states $i_{k}$ using the distribution $\xi$
- Generating many samples of transitions $\left(i_{k}, j_{k}\right)$ using the policy $\mu$
- Form a simulation-based approximation of the optimality condition for projection problem or problem $\left(^{*}\right.$ ) (use sample averages in place of inner products)
- Solve the Monte-Carlo approximation of the optimality condition
- Issues for indirect methods: How to generate the samples? How to calculate $r^{*}$ efficiently?

## ANOTHER INDIRECT METHOD: AGGREGATION

- A first idea: Group similar states together into "aggregate states" $x_{1}, \ldots, x_{s}$; assign a common cost value $r_{i}$ to each group $x_{i}$.
- Solve an "aggregate" DP problem, involving the aggregate states, to obtain $r=\left(r_{1}, \ldots, r_{s}\right)$. This is called hard aggregation

$$
\begin{aligned}
& \begin{array}{|ccc|c|}
\hline \bullet^{1} & & \bullet^{2} & \bullet^{3} \\
\bullet^{4} & x_{1} & & x_{2} \\
\hline & & \bullet & \bullet^{6} \\
\hline & \bullet^{7} & x_{3} & \bullet^{8} \\
& & x_{4} & \bullet^{9} \\
\hline
\end{array} \\
& \Phi=\left(\begin{array}{llll}
1 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{array}\right)
\end{aligned}
$$

- More general/mathematical view: Solve

$$
\Phi r=\Phi D T_{\mu}(\Phi r)
$$

where the rows of $D$ and $\Phi$ are prob. distributions (e.g., $D$ and $\Phi$ "aggregate" rows and columns of the linear system $J=T_{\mu} J$ )

- Compare with projected equation $\Phi r=\Pi T_{\mu}(\Phi r)$. Note: $\Phi D$ is a projection in some interesting cases

## AGGREGATION AS PROBLEM APPROXIMATION

- Aggregation can be viewed as a systematic approach for problem approximation. Main elements:
- Solve (exactly or approximately) the "aggregate" problem by any kind of VI or PI method (including simulation-based methods)
- Use the optimal cost of the aggregate problem to approximate the optimal cost of the original problem
- Because an exact PI algorithm is used to solve the approximate/aggregate problem the method behaves more regularly than the projected equation approach

## APPROXIMATE POLICY ITERATION

ISSUES

## THEORETICAL BASIS OF APPROXIMATE PI

- If policies are approximately evaluated using an approximation architecture such that

$$
\max _{i}\left|\tilde{J}\left(i, r_{k}\right)-J_{\mu^{k}}(i)\right| \leq \delta, \quad k=0,1, \ldots
$$

- If policy improvement is also approximate,

$$
\max _{i}\left|\left(T_{\mu^{k+1}} \tilde{J}\right)\left(i, r_{k}\right)-(T \tilde{J})\left(i, r_{k}\right)\right| \leq \epsilon, \quad k=0,1, \ldots
$$

- Error bound: The sequence $\left\{\mu^{k}\right\}$ generated by approximate policy iteration satisfies

$$
\limsup _{k \rightarrow \infty} \max _{i}\left(J_{\mu^{k}}(i)-J^{*}(i)\right) \leq \frac{\epsilon+2 \alpha \delta}{(1-\alpha)^{2}}
$$

- Typical practical behavior: The method makes steady progress up to a point and then the iterates $J_{\mu^{k}}$ oscillate within a neighborhood of $J^{*}$.
- Oscillations are quite unpredictable.
- Some bad examples of oscillations have been constructed.
- In practice oscillations between policies is probably not the major concern.

## THE ISSUE OF EXPLORATION

- To evaluate a policy $\mu$, we need to generate cost samples using that policy - this biases the simulation by underrepresenting states that are unlikely to occur under $\mu$
- Cost-to-go estimates of underrepresented states may be highly inaccurate
- This seriously impacts the improved policy $\bar{\mu}$
- This is known as inadequate exploration - a particularly acute difficulty when the randomness embodied in the transition probabilities is "relatively small" (e.g., a deterministic system)
- Some remedies:
- Frequently restart the simulation and ensure that the initial states employed form a rich and representative subset
- Occasionally generate transitions that use a randomly selected control rather than the one dictated by the policy $\mu$
- Other methods: Use two Markov chains (one is the chain of the policy and is used to generate the transition sequence, the other is used to generate the state sequence).

## APPROXIMATING Q-FACTORS

- Given $\tilde{J}(i ; r)$, policy improvement requires a model [knowledge of $p_{i j}(u)$ for all controls $u \in$ $U(i)]$
- Model-free alternative: Approximate $Q$-factors

$$
\tilde{Q}(i, u ; r) \approx \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J_{\mu}(j)\right)
$$

and use for policy improvement the minimization

$$
\bar{\mu}(i) \in \arg \min _{u \in U(i)} \tilde{Q}(i, u ; r)
$$

- $r$ is an adjustable parameter vector and $\tilde{Q}(i, u ; r)$ is a parametric architecture, such as

$$
\tilde{Q}(i, u ; r)=\sum_{m=1}^{s} r_{m} \phi_{m}(i, u)
$$

- We can adapt any of the cost approximation approaches, e.g., projected equations, aggregation - Use the Markov chain with states $(i, u)$, so $p_{i j}(\mu(i))$ is the transition prob. to $(j, \mu(i)), 0$ to other $\left(j, u^{\prime}\right)$
- Major concern: Acutely diminished exploration

## SOME GENERAL ISSUES

## STOCHASTIC ALGORITHMS: GENERALITIES

- Consider solution of a linear equation $x=b+$ $A x$ by using $m$ simulation samples $b+w_{k}$ and $A+W_{k}, k=1, \ldots, m$, where $w_{k}, W_{k}$ are random, e.g., "simulation noise"
- Think of $x=b+A x$ as approximate policy evaluation (projected or aggregation equations)
- Stoch. approx. (SA) approach: For $k=1, \ldots, m$

$$
x_{k+1}=\left(1-\gamma_{k}\right) x_{k}+\gamma_{k}\left(\left(b+w_{k}\right)+\left(A+W_{k}\right) x_{k}\right)
$$

- Monte Carlo estimation (MCE) approach: Form Monte Carlo estimates of $b$ and $A$

$$
b_{m}=\frac{1}{m} \sum_{k=1}^{m}\left(b+w_{k}\right), \quad A_{m}=\frac{1}{m} \sum_{k=1}^{m}\left(A+W_{k}\right)
$$

Then solve $x=b_{m}+A_{m} x$ by matrix inversion

$$
x_{m}=\left(1-A_{m}\right)^{-1} b_{m}
$$

or iteratively

- $\mathrm{TD}(\lambda)$ and $Q$-learning are SA methods
- LSTD $(\lambda)$ and LSPE $(\lambda)$ are MCE methods

## COSTS OR COST DIFFERENCES?

- Consider the exact policy improvement process. To compare two controls $u$ and $u^{\prime}$ at $x$, we need

$$
E\left\{g(x, u, w)-g\left(x, u^{\prime}, w\right)+\alpha\left(J_{\mu}(\bar{x})-J_{\mu}\left(\bar{x}^{\prime}\right)\right)\right\}
$$

where $\bar{x}=f(x, u, w)$ and $\bar{x}^{\prime}=f\left(x, u^{\prime}, w\right)$

- Approximate $J_{\mu}(\bar{x})$ or

$$
D_{\mu}\left(\bar{x}, \bar{x}^{\prime}\right)=J_{\mu}(\bar{x})-J_{\mu}\left(\bar{x}^{\prime}\right) ?
$$

- Approximating $D_{\mu}\left(\bar{x}, \bar{x}^{\prime}\right)$ avoids "noise differencing". This can make a big difference
- Important point: $D_{\mu}$ satisfies a Bellman equation for a system with "state" $\left(x, x^{\prime}\right)$

$$
D_{\mu}\left(x, x^{\prime}\right)=E\left\{G_{\mu}\left(x, x^{\prime}, w\right)+\alpha D_{\mu}\left(\bar{x}, \bar{x}^{\prime}\right)\right\}
$$

where $\bar{x}=f(x, \mu(x), w), \bar{x}^{\prime}=f\left(x^{\prime}, \mu\left(x^{\prime}\right), w\right)$ and

$$
G_{\mu}\left(x, x^{\prime}, w\right)=g(x, \mu(x), w)-g\left(x^{\prime}, \mu\left(x^{\prime}\right), w\right)
$$

- $D_{\mu}$ can be "learned" by the standard methods (TD, LSTD, LSPE, Bellman error, aggregation, etc). This is known as differential training.

## AN EXAMPLE (FROM THE NDP TEXT)

- System and cost per stage:

$$
x_{k+1}=x_{k}+\delta u_{k}, \quad g(x, u)=\delta\left(x^{2}+u^{2}\right)
$$

$\delta>0$ is very small; think of discretization of continuous-time problem involving $d x(t) / d t=u(t)$

- Consider policy $\mu(x)=-2 x$. Its cost function is

$$
J_{\mu}(x)=\frac{5 x^{2}}{4}(1+\delta)+O\left(\delta^{2}\right)
$$

and its Q-factor is

$$
Q_{\mu}(x, u)=\frac{5 x^{2}}{4}+\delta\left(\frac{9 x^{2}}{4}+u^{2}+\frac{5}{2} x u\right)+O\left(\delta^{2}\right)
$$

- The important part for policy improvement is

$$
\delta\left(u^{2}+\frac{5}{2} x u\right)
$$

When $J_{\mu}(x)\left[\right.$ or $\left.Q_{\mu}(x, u)\right]$ is approximated by $\tilde{J}_{\mu}(x ; r)$ or by $\left.\tilde{Q}_{\mu}(x, u ; r)\right]$, it will be dominated by $\frac{5 x^{2}}{4}$ and will be "lost"

# 6.231 DYNAMIC PROGRAMMING 

## LECTURE 4

## LECTURE OUTLINE

- Review of approximation in value space
- Approximate VI and PI
- Projected Bellman equations
- Matrix form of the projected equation
- Simulation-based implementation
- LSTD and LSPE methods
- Optimistic versions
- Multistep projected Bellman equations
- Bias-variance tradeoff

## REVIEW

## DISCOUNTED MDP

- System: Controlled Markov chain with states $i=1, \ldots, n$, and finite control set $U(i)$ at state $i$ - Transition probabilities: $p_{i j}(u)$

- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$ starting at state $i$ :

$$
J_{\pi}(i)=\lim _{N \rightarrow \infty} E\left\{\sum_{k=0}^{N} \alpha^{k} g\left(i_{k}, \mu_{k}\left(i_{k}\right), i_{k+1}\right) \mid i_{0}=i\right\}
$$

with $\alpha \in[0,1)$

- Shorthand notation for DP mappings

$$
\begin{aligned}
& (T J)(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha J(j)), \quad i=1, \ldots, n, \\
& \left(T_{\mu} J\right)(i)=\sum_{j=1}^{n} p_{i j}(\mu(i))(g(i, \mu(i), j)+\alpha J(j)), \quad i=1, \ldots, n
\end{aligned}
$$

## "SHORTHAND" THEORY - A SUMMARY

- Bellman's equation: $J^{*}=T J^{*}, J_{\mu}=T_{\mu} J_{\mu}$ or

$$
J^{*}(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J^{*}(j)\right), \quad \forall i
$$

$$
J_{\mu}(i)=\sum_{j=1}^{n} p_{i j}(\mu(i))\left(g(i, \mu(i), j)+\alpha J_{\mu}(j)\right), \quad \forall i
$$

- Optimality condition:
$\mu:$ optimal $<==>\quad T_{\mu} J^{*}=T J^{*}$
i.e.,
$\mu(i) \in \arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J^{*}(j)\right), \quad \forall i$

# THE TWO MAIN ALGORITHMS: VI AND PI 

- Value iteration: For any $J \in \Re^{n}$

$$
J^{*}(i)=\lim _{k \rightarrow \infty}\left(T^{k} J\right)(i), \quad \forall i=1, \ldots, n
$$

- Policy iteration: Given $\mu^{k}$
- Policy evaluation: Find $J_{\mu^{k}}$ by solving

$$
\begin{aligned}
J_{\mu^{k}}(i) & =\sum_{j=1}^{n} p_{i j}\left(\mu^{k}(i)\right)\left(g\left(i, \mu^{k}(i), j\right)+\alpha J_{\mu^{k}}(j)\right), \quad i=1, \ldots, n \\
& \text { or } J_{\mu^{k}}=T_{\mu^{k}} J_{\mu^{k}} \\
- & \text { Policy improvement: Let } \mu^{k+1} \text { be such that }
\end{aligned}
$$

$$
\begin{aligned}
& \mu^{k+1}(i) \in \arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J_{\mu^{k}}(j)\right), \quad \forall i \\
& \quad \text { or } T_{\mu^{k+1}} J_{\mu^{k}}=T J_{\mu^{k}}
\end{aligned}
$$

- Policy evaluation is equivalent to solving an $n \times n$ linear system of equations
- For large $n$, exact PI is out of the question (even though it terminates finitely)

## APPROXIMATION IN VALUE SPACE

- Approximate $J^{*}$ or $J_{\mu}$ from a parametric class $\tilde{J}(i ; r)$, where $i$ is the current state and $r=\left(r_{1}, \ldots, r_{s}\right)$ is a vector of "tunable" scalars weights
- Think $n$ : HUGE, $s$ : (Relatively) SMALL
- Many types of approximation architectures [i.e., parametric classes $\tilde{J}(i ; r)]$ to select from
- Any $r \in \Re^{s}$ defines a (suboptimal) one-step lookahead policy
$\tilde{\mu}(i)=\arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha \tilde{J}(j ; r)), \quad \forall i$
- We want to find a "good" $r$
- We will focus mostly on linear architectures

$$
\tilde{J}(r)=\Phi r
$$

where $\Phi$ is an $n \times s$ matrix whose columns are viewed as basis functions

## LINEAR APPROXIMATION ARCHITECTURES

- We have

$$
\tilde{J}(i ; r)=\phi(i)^{\prime} r, \quad i=1, \ldots, n
$$

where $\phi(i)^{\prime}, i=1, \ldots, n$ is the $i$ th row of $\Phi$, or

$$
\tilde{J}(r)=\Phi r=\sum_{j=1}^{s} \Phi_{j} r_{j}
$$

where $\Phi_{j}$ is the $j$ th column of $\Phi$

- This is approximation on the subspace

$$
S=\left\{\Phi r \mid r \in \Re^{s}\right\}
$$

spanned by the columns of $\Phi$ (basis functions)

- Many examples of feature types: Polynomial approximation, radial basis functions, etc
- Instead of computing $J_{\mu}$ or $J^{*}$, which is hugedimensional, we compute the low-dimensional $r=$ ( $r_{1}, \ldots, r_{s}$ ) using low-dimensional calculations

## APPROXIMATE VALUE ITERATION

## APPROXIMATE (FITTED) VI

- Approximates sequentially $J_{k}(i)=\left(T^{k} J_{0}\right)(i)$, $k=1,2, \ldots$, with $\tilde{J}_{k}\left(i ; r_{k}\right)$
- The starting function $J_{0}$ is given (e.g., $J_{0} \equiv 0$ ) - Approximate (Fitted) Value Iteration: A sequential "fit" to produce $\widetilde{J}_{k+1}$ from $\tilde{J}_{k}$, i.e., $\tilde{J}_{k+1} \approx$ $T \tilde{J}_{k}$ or (for a single policy $\mu$ ) $\tilde{J}_{k+1} \approx T_{\mu} \tilde{J}_{k}$

Fitted Value Iteration

- After a large enough number $N$ of steps, $\tilde{J}_{N}\left(i ; r_{N}\right)$ is used as approximation $\tilde{J}(i ; r)$ to $J^{*}(i)$
- Possibly use (approximate) projection $\Pi$ with respect to some projection norm,

$$
\tilde{J}_{k+1} \approx \Pi T \tilde{J}_{k}
$$

## WEIGHTED EUCLIDEAN PROJECTIONS

- Consider a weighted Euclidean norm

$$
\|J\|_{\xi}=\sqrt{\sum_{i=1}^{n} \xi_{i}(J(i))^{2}}
$$

where $\xi=\left(\xi_{1}, \ldots, \xi_{n}\right)$ is a positive distribution ( $\xi_{i}>0$ for all $i$ ).

- Let $\Pi$ denote the projection operation onto

$$
S=\left\{\Phi r \mid r \in \Re^{s}\right\}
$$

with respect to this norm, i.e., for any $J \in \Re^{n}$,

$$
\Pi J=\Phi r^{*}
$$

where

$$
r^{*}=\arg \min _{r \in \Re^{s}}\|\Phi r-J\|_{\xi}^{2}
$$

- Recall that weighted Euclidean projection can be implemented by simulation and least squares, i.e., sampling $J(i)_{k}$ according to $\xi$ and solving

$$
\min _{r \in \Re^{s}} \sum_{t=1}\left(\phi\left(i_{t}\right)^{\prime} r-J\left(i_{t}\right)\right)^{2}
$$

## FITTED VI - NAIVE IMPLEMENTATION

- Select/sample a "small" subset $I_{k}$ of representative states
- For each $i \in I_{k}$, given $\tilde{J}_{k}$, compute

$$
\left(T \tilde{J}_{k}\right)(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \tilde{J}_{k}(j ; r)\right)
$$

- "Fit" the function $\tilde{J}_{k+1}\left(i ; r_{k+1}\right)$ to the "small" set of values $\left(T \tilde{J}_{k}\right)(i), i \in I_{k}$ (for example use some form of approximate projection)
- Simulation can be used for "model-free" implementation
- Error Bound: If the fit is uniformly accurate within $\delta>0$, i.e.,

$$
\max _{i}\left|\tilde{J}_{k+1}(i)-T \tilde{J}_{k}(i)\right| \leq \delta,
$$

then

$$
\lim \sup _{k \rightarrow \infty} \max _{i=1, \ldots, n}\left(\tilde{J}_{k}\left(i, r_{k}\right)-J^{*}(i)\right) \leq \frac{2 \alpha \delta}{(1-\alpha)^{2}}
$$

- But there is a potential problem!

## AN EXAMPLE OF FAILURE

- Consider two-state discounted MDP with states 1 and 2, and a single policy.
- Deterministic transitions: $1 \rightarrow 2$ and $2 \rightarrow 2$
- Transition costs $\equiv 0$, so $J^{*}(1)=J^{*}(2)=0$.
- Consider (exact) fitted VI scheme that approximates cost functions within $S=\{(r, 2 r) \mid r \in \Re\}$ with a weighted least squares fit; here $\Phi=\binom{1}{2}$
- Given $\tilde{J}_{k}=\left(r_{k}, 2 r_{k}\right)$, we find $\tilde{J}_{k+1}=\left(r_{k+1}, 2 r_{k+1}\right)$, where $\tilde{J}_{k+1}=\Pi_{\xi}\left(T \tilde{J}_{k}\right)$, with weights $\xi=\left(\xi_{1}, \xi_{2}\right)$ : $r_{k+1}=\arg \min _{r}\left[\xi_{1}\left(r-\left(T \tilde{J}_{k}\right)(1)\right)^{2}+\xi_{2}\left(2 r-\left(T \tilde{J}_{k}\right)(2)\right)^{2}\right]$
- With straightforward calculation $r_{k+1}=\alpha \beta r_{k}, \quad$ where $\beta=2\left(\xi_{1}+2 \xi_{2}\right) /\left(\xi_{1}+4 \xi_{2}\right)>1$
- So if $\alpha>1 / \beta$ (e.g., $\xi_{1}=\xi_{2}=1$ ), the sequence $\left\{r_{k}\right\}$ diverges and so does $\left\{\tilde{J}_{k}\right\}$.
- Difficulty is that $T$ is a contraction, but $\Pi_{\xi} T$ (= least squares fit composed with $T$ ) is not.

## NORM MISMATCH PROBLEM

- For the method to converge, we need $\Pi_{\xi} T$ to be a contraction; the contraction property of $T$ is not enough

Fitted Value Iteration with Projection

- We need a vector of weights $\xi$ such that $T$ is a contraction with respect to the weighted Euclidean norm $\|\cdot\|_{\xi}$
- Then we can show that $\Pi_{\xi} T$ is a contraction with respect to $\|\cdot\|_{\xi}$
- We will come back to this issue

## APPROXIMATE POLICY ITERATION

## APPROXIMATE PI

Approximate Policy Evaluation

Policy Improvement

- Evaluation of typical policy $\mu$ : Linear cost function approximation $\tilde{J}_{\mu}(r)=\Phi r$, where $\Phi$ is full rank $n \times s$ matrix with columns the basis functions, and $i$ th row denoted $\phi(i)^{\prime}$.
- Policy "improvement" to generate $\bar{\mu}$ :

$$
\bar{\mu}(i)=\arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \phi(j)^{\prime} r\right)
$$

- Error Bound (same as approximate VI): If

$$
\max _{i}\left|\tilde{J}_{\mu^{k}}\left(i, r_{k}\right)-J_{\mu^{k}}(i)\right| \leq \delta, \quad k=0,1, \ldots
$$

the sequence $\left\{\mu^{k}\right\}$ satisfies

$$
\limsup _{k \rightarrow \infty} \max _{i}\left(J_{\mu^{k}}(i)-J^{*}(i)\right) \leq \frac{2 \alpha \delta}{(1-\alpha)^{2}}
$$

## POLICY EVALUATION

- Let's consider approximate evaluation of the cost of the current policy by using simulation.
- Direct policy evaluation - Cost samples generated by simulation, and optimization by least squares
- Indirect policy evaluation - solving the projected equation $\Phi r=\Pi T_{\mu}(\Phi r)$ where $\Pi$ is projection w/ respect to a suitable weighted Euclidean norm

Direct Method: Projection of cost vector $J_{\mu}$

Indirect Method: Solving a projected form of Bellman's equation

- Recall that projection can be implemented by simulation and least squares

## PI WITH INDIRECT POLICY EVALUATION

Approximate Policy Evaluation

- Given the current policy $\mu$ :
- We solve the projected Bellman's equation

$$
\Phi r=\Pi T_{\mu}(\Phi r)
$$

- We approximate the solution $J_{\mu}$ of Bellman's equation

$$
J=T_{\mu} J
$$

with the projected equation solution $\tilde{J}_{\mu}(r)$

## KEY QUESTIONS AND RESULTS

- Does the projected equation have a solution?
- Under what conditions is the mapping $\Pi T_{\mu}$ a contraction, so $\Pi T_{\mu}$ has unique fixed point?
- Assumption: The Markov chain corresponding to $\mu$ has a single recurrent class and no transient states, i.e., it has steady-state probabilities that are positive

$$
\xi_{j}=\lim _{N \rightarrow \infty} \frac{1}{N} \sum_{k=1}^{N} P\left(i_{k}=j \mid i_{0}=i\right)>0
$$

Note that $\xi_{j}$ is the long-term frequency of state $j$. - Proposition: (Norm Matching Property) Assume that the projection $\Pi$ is with respect to $\|\cdot\|_{\xi}$, where $\xi=\left(\xi_{1}, \ldots, \xi_{n}\right)$ is the steady-state probability vector. Then:
(a) $\Pi T_{\mu}$ is contraction of modulus $\alpha$ with respect to $\|\cdot\|_{\xi}$.
(b) The unique fixed point $\Phi r^{*}$ of $\Pi T_{\mu}$ satisfies

$$
\left\|J_{\mu}-\Phi r^{*}\right\|_{\xi} \leq \frac{1}{\sqrt{1-\alpha^{2}}}\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}
$$

## PRELIMINARIES: PROJECTION PROPERTIES

- Important property of the projection $\Pi$ on $S$ with weighted Euclidean norm $\|\cdot\|_{\xi}$. For all $J \in$ $\Re^{n}, \Phi r \in S$, the Pythagorean Theorem holds:

$$
\|J-\Phi r\|_{\xi}^{2}=\|J-\Pi J\|_{\xi}^{2}+\|\Pi J-\Phi r\|_{\xi}^{2}
$$

- The Pythagorean Theorem implies that the projection is nonexpansive, i.e.,

$$
\|\Pi J-\Pi \bar{J}\|_{\xi} \leq\|J-\bar{J}\|_{\xi}, \quad \text { for all } J, \bar{J} \in \Re^{n}
$$

To see this, note that

$$
\begin{aligned}
\|\Pi(J-\bar{J})\|_{\xi}^{2} & \leq\|\Pi(J-\bar{J})\|_{\xi}^{2}+\|(I-\Pi)(J-\bar{J})\|_{\xi}^{2} \\
& =\|J-\bar{J}\|_{\xi}^{2}
\end{aligned}
$$

## PROOF OF CONTRACTION PROPERTY

- Lemma: If $P$ is the transition matrix of $\mu$,

$$
\|P z\|_{\xi} \leq\|z\|_{\xi}, \quad z \in \Re^{n}
$$

Proof: Let $p_{i j}$ be the components of $P$. For all $z \in \Re^{n}$, we have

$$
\begin{aligned}
\|P z\|_{\xi}^{2} & =\sum_{i=1}^{n} \xi_{i}\left(\sum_{j=1}^{n} p_{i j} z_{j}\right)^{2} \leq \sum_{i=1}^{n} \xi_{i} \sum_{j=1}^{n} p_{i j} z_{j}^{2} \\
& =\sum_{j=1}^{n} \sum_{i=1}^{n} \xi_{i} p_{i j} z_{j}^{2}=\sum_{j=1}^{n} \xi_{j} z_{j}^{2}=\|z\|_{\xi}^{2},
\end{aligned}
$$

where the inequality follows from the convexity of the quadratic function, and the next to last equality follows from the defining property $\sum_{i=1}^{n} \xi_{i} p_{i j}=$ $\xi_{j}$ of the steady-state probabilities.

- Using the lemma, the nonexpansiveness of $\Pi$, and the definition $T_{\mu} J=g+\alpha P J$, we have
$\left\|\Pi T_{\mu} J-\Pi T_{\mu} \bar{J}\right\|_{\xi} \leq\left\|T_{\mu} J-T_{\mu} \bar{J}\right\|_{\xi}=\alpha\|P(J-\bar{J})\|_{\xi} \leq \alpha\|J-\bar{J}\|_{\xi}$ for all $J, \bar{J} \in \Re^{n}$. Hence $\Pi T_{\mu}$ is a contraction of modulus $\alpha$.

## PROOF OF ERROR BOUND

- Let $\Phi r^{*}$ be the fixed point of $\Pi T$. We have

$$
\left\|J_{\mu}-\Phi r^{*}\right\|_{\xi} \leq \frac{1}{\sqrt{1-\alpha^{2}}}\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}
$$

Proof: We have

$$
\begin{aligned}
\left\|J_{\mu}-\Phi r^{*}\right\|_{\xi}^{2} & =\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}^{2}+\left\|\Pi J_{\mu}-\Phi r^{*}\right\|_{\xi}^{2} \\
& =\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}^{2}+\left\|\Pi T J_{\mu}-\Pi T\left(\Phi r^{*}\right)\right\|_{\xi}^{2} \\
& \leq\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}^{2}+\alpha^{2}\left\|J_{\mu}-\Phi r^{*}\right\|_{\xi}^{2}
\end{aligned}
$$

where

- The first equality uses the Pythagorean Theorem
- The second equality holds because $J_{\mu}$ is the fixed point of $T$ and $\Phi r^{*}$ is the fixed point of $П Т$
- The inequality uses the contraction property of $\Pi Т$.
Q.E.D.

## SIMULATION-BASED SOLUTION OF PROJECTED EQUATION

## MATRIX FORM OF PROJECTED EQUATION

- The solution $\Phi r^{*}$ satisfies the orthogonality condition: The error

$$
\Phi r^{*}-\left(g+\alpha P \Phi r^{*}\right)
$$

is "orthogonal" to the subspace spanned by the columns of $\Phi$.

- This is written as

$$
\Phi^{\prime} \Xi\left(\Phi r^{*}-\left(g+\alpha P \Phi r^{*}\right)\right)=0,
$$

where $\Xi$ is the diagonal matrix with the steadystate probabilities $\xi_{1}, \ldots, \xi_{n}$ along the diagonal.

- Equivalently, $C r^{*}=d$, where

$$
C=\Phi^{\prime} \Xi(I-\alpha P) \Phi, \quad d=\Phi^{\prime} \Xi g
$$

but computing $C$ and $d$ is HARD (high-dimensional inner products).

## SOLUTION OF PROJECTED EQUATION

- Solve $C r^{*}=d$ by matrix inversion: $r^{*}=C^{-1} d$
- Projected Value Iteration (PVI) method:

$$
\Phi r_{k+1}=\Pi T\left(\Phi r_{k}\right)=\Pi\left(g+\alpha P \Phi r_{k}\right)
$$

Converges to $r^{*}$ because $\Pi T$ is a contraction.

- PVI can be written as:

$$
r_{k+1}=\arg \min _{r \in \Re^{s}}\left\|\Phi r-\left(g+\alpha P \Phi r_{k}\right)\right\|_{\xi}^{2}
$$

By setting to 0 the gradient with respect to $r$,

$$
\Phi^{\prime} \Xi\left(\Phi r_{k+1}-\left(g+\alpha P \Phi r_{k}\right)\right)=0
$$

which yields

$$
r_{k+1}=r_{k}-\left(\Phi^{\prime} \Xi \Phi\right)^{-1}\left(C r_{k}-d\right)
$$

## SIMULATION-BASED IMPLEMENTATIONS

- Key idea: Calculate simulation-based approximations based on $k$ samples

$$
C_{k} \approx C, \quad d_{k} \approx d
$$

- Matrix inversion $r^{*}=C^{-1} d$ is approximated by

$$
\hat{r}_{k}=C_{k}^{-1} d_{k}
$$

This is the LSTD (Least Squares Temporal Differences) Method.

- PVI method $r_{k+1}=r_{k}-\left(\Phi^{\prime} \Xi \Phi\right)^{-1}\left(C r_{k}-d\right)$ is approximated by

$$
r_{k+1}=r_{k}-G_{k}\left(C_{k} r_{k}-d_{k}\right)
$$

where

$$
G_{k} \approx\left(\Phi^{\prime} \Xi \Phi\right)^{-1}
$$

This is the LSPE (Least Squares Policy Evaluation) Method.

- Key fact: $C_{k}, d_{k}$, and $G_{k}$ can be computed with low-dimensional linear algebra (of order $s$; the number of basis functions).

## SIMULATION MECHANICS

- We generate an infinitely long trajectory $\left(i_{0}, i_{1}, \ldots\right)$ of the Markov chain, so states $i$ and transitions $(i, j)$ appear with long-term frequencies $\xi_{i}$ and $p_{i j}$.
- After generating each transition $\left(i_{t}, i_{t+1}\right)$, we compute the row $\phi\left(i_{t}\right)^{\prime}$ of $\Phi$ and the cost component $g\left(i_{t}, i_{t+1}\right)$.
- We form

$$
\begin{aligned}
& d_{k}=\frac{1}{k+1} \sum_{t=0}^{k} \phi\left(i_{t}\right) g\left(i_{t}, i_{t+1}\right) \approx \sum_{i, j} \xi_{i} p_{i j} \phi(i) g(i, j)=\Phi^{\prime} \Xi g=d \\
& C_{k}=\frac{1}{k+1} \sum_{t=0}^{k} \phi\left(i_{t}\right)\left(\phi\left(i_{t}\right)-\alpha \phi\left(i_{t+1}\right)\right)^{\prime} \approx \Phi^{\prime} \Xi(I-\alpha P) \Phi=C
\end{aligned}
$$

Also in the case of LSPE

$$
G_{k}=\frac{1}{k+1} \sum_{t=0}^{k} \phi\left(i_{t}\right) \phi\left(i_{t}\right)^{\prime} \approx \Phi^{\prime} \Xi \Phi
$$

- Convergence based on law of large numbers.
- $C_{k}, d_{k}$, and $G_{k}$ can be formed incrementally. Also can be written using the formalism of temporal differences (this is just a matter of style)

## OPTIMISTIC VERSIONS

- Instead of calculating nearly exact approximations $C_{k} \approx C$ and $d_{k} \approx d$, we do a less accurate approximation, based on few simulation samples
- Evaluate (coarsely) current policy $\mu$, then do a policy improvement
- This often leads to faster computation (as optimistic methods often do)
- Very complex behavior (see the subsequent discussion on oscillations)
- The matrix inversion/LSTD method has serious problems due to large simulation noise (because of limited sampling) - particularly if the $C$ matrix is ill-conditioned
- LSPE tends to cope better because of its iterative nature (this is true of other iterative methods as well)
- A stepsize $\gamma \in(0,1]$ in LSPE may be useful to damp the effect of simulation noise

$$
r_{k+1}=r_{k}-\gamma G_{k}\left(C_{k} r_{k}-d_{k}\right)
$$

## MULTISTEP PROJECTED EQUATIONS

## MULTISTEP METHODS

- Introduce a multistep version of Bellman's equation $J=T^{(\lambda)} J$, where for $\lambda \in[0,1)$,

$$
T^{(\lambda)}=(1-\lambda) \sum_{\ell=0}^{\infty} \lambda^{\ell} T^{\ell+1}
$$

Geometrically weighted sum of powers of $T$.

- Note that $T^{\ell}$ is a contraction with modulus $\alpha^{\ell}$, with respect to the weighted Euclidean norm $\|\cdot\|_{\xi}$, where $\xi$ is the steady-state probability vector of the Markov chain.
- Hence $T^{(\lambda)}$ is a contraction with modulus

$$
\alpha_{\lambda}=(1-\lambda) \sum_{\ell=0}^{\infty} \alpha^{\ell+1} \lambda^{\ell}=\frac{\alpha(1-\lambda)}{1-\alpha \lambda}
$$

Note that $\alpha_{\lambda} \rightarrow 0$ as $\lambda \rightarrow 1$

- $T^{\ell}$ and $T^{(\lambda)}$ have the same fixed point $J_{\mu}$ and

$$
\left\|J_{\mu}-\Phi r_{\lambda}^{*}\right\|_{\xi} \leq \frac{1}{\sqrt{1-\alpha_{\lambda}^{2}}}\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}
$$

where $\Phi r_{\lambda}^{*}$ is the fixed point of $\Pi T^{(\lambda)}$.

- The fixed point $\Phi r_{\lambda}^{*}$ depends on $\lambda$.

## BIAS-VARIANCE TRADEOFF

- Error bound $\left\|J_{\mu}-\Phi r_{\lambda}^{*}\right\|_{\xi} \leq \frac{1}{\sqrt{1-\alpha_{\lambda}^{2}}}\left\|J_{\mu}-\Pi J_{\mu}\right\|_{\xi}$
- As $\lambda \uparrow 1$, we have $\alpha_{\lambda} \downarrow 0$, so error bound (and the quality of approximation) improves as $\lambda \uparrow 1$. In fact

$$
\lim _{\lambda \uparrow 1} \Phi r_{\lambda}^{*}=\Pi J_{\mu}
$$

- But the simulation noise in approximating

$$
T^{(\lambda)}=(1-\lambda) \sum_{\ell=0}^{\infty} \lambda^{\ell} T^{\ell+1}
$$

## increases

- Choice of $\lambda$ is usually based on trial and error

## MULTISTEP PROJECTED EQ. METHODS

- The projected Bellman equation is

$$
\Phi r=\Pi T^{(\lambda)}(\Phi r)
$$

- In matrix form: $C^{(\lambda)} r=d^{(\lambda)}$, where

$$
C^{(\lambda)}=\Phi^{\prime} \Xi\left(I-\alpha P^{(\lambda)}\right) \Phi, \quad d^{(\lambda)}=\Phi^{\prime} \Xi g^{(\lambda)},
$$

with

$$
P^{(\lambda)}=(1-\lambda) \sum_{\ell=0}^{\infty} \alpha^{\ell} \lambda^{\ell} P^{\ell+1}, \quad g^{(\lambda)}=\sum_{\ell=0}^{\infty} \alpha^{\ell} \lambda^{\ell} P^{\ell} g
$$

- The $\operatorname{LSTD}(\lambda)$ method is

$$
\left(C_{k}^{(\lambda)}\right)^{-1} d_{k}^{(\lambda)},
$$

where $C_{k}^{(\lambda)}$ and $d_{k}^{(\lambda)}$ are simulation-based approximations of $C^{(\lambda)}$ and $d^{(\lambda)}$.

- The $\operatorname{LSPE}(\lambda)$ method is

$$
r_{k+1}=r_{k}-\gamma G_{k}\left(C_{k}^{(\lambda)} r_{k}-d_{k}^{(\lambda)}\right)
$$

where $G_{k}$ is a simulation-based approx. to $\left(\Phi^{\prime} \Xi \Phi\right)^{-1}$

- $\mathrm{TD}(\lambda)$ : An important simpler/slower iteration [similar to $\operatorname{LSPE}(\lambda)$ with $G_{k}=I$ - see the text].

## MORE ON MULTISTEP METHODS

- The simulation process to obtain $C_{k}^{(\lambda)}$ and $d_{k}^{(\lambda)}$ is similar to the case $\lambda=0$ (single simulation trajectory $i_{0}, i_{1}, \ldots$, more complex formulas)

$$
\begin{gathered}
C_{k}^{(\lambda)}=\frac{1}{k+1} \sum_{t=0}^{k} \phi\left(i_{t}\right) \sum_{m=t}^{k} \alpha^{m-t} \lambda^{m-t}\left(\phi\left(i_{m}\right)-\alpha \phi\left(i_{m+1}\right)\right)^{\prime} \\
d_{k}^{(\lambda)}=\frac{1}{k+1} \sum_{t=0}^{k} \phi\left(i_{t}\right) \sum_{m=t}^{k} \alpha^{m-t} \lambda^{m-t} g_{i_{m}}
\end{gathered}
$$

- In the context of approximate policy iteration, we can use optimistic versions (few samples between policy updates).
- Many different versions (see the text).
- Note the $\lambda$-tradeoffs:
- As $\lambda \uparrow 1, C_{k}^{(\lambda)}$ and $d_{k}^{(\lambda)}$ contain more "simulation noise", so more samples are needed for a close approximation of $r_{\lambda}$ (the solution of the projected equation)
- The error bound $\left\|J_{\mu}-\Phi r_{\lambda}\right\|_{\xi}$ becomes smaller
- As $\lambda \uparrow 1, \Pi T^{(\lambda)}$ becomes a contraction for arbitrary projection norm

## LECTURE 5

## LECTURE OUTLINE

- Review of approximate PI based on projected Bellman equations
- Issues of policy improvement
- Exploration enhancement in policy evaluation
- Oscillations in approximate PI
- Aggregation - An alternative to the projected equation/Galerkin approach
- Examples of aggregation
- Simulation-based aggregation
- Relation between aggregation and projected equations

## REVIEW

## DISCOUNTED MDP

- System: Controlled Markov chain with states $i=1, \ldots, n$ and finite set of controls $u \in U(i)$
- Transition probabilities: $p_{i j}(u)$

- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$ starting at state $i$ :

$$
J_{\pi}(i)=\lim _{N \rightarrow \infty} E\left\{\sum_{k=0}^{N} \alpha^{k} g\left(i_{k}, \mu_{k}\left(i_{k}\right), i_{k+1}\right) \mid i=i_{0}\right\}
$$

with $\alpha \in[0,1)$

- Shorthand notation for DP mappings

$$
\begin{aligned}
& (T J)(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha J(j)), \quad i=1, \ldots, n, \\
& \left(T_{\mu} J\right)(i)=\sum_{j=1}^{n} p_{i j}(\mu(i))(g(i, \mu(i), j)+\alpha J(j)), \quad i=1, \ldots, n
\end{aligned}
$$

## APPROXIMATE PI

- Evaluation of typical policy $\mu$ : Linear cost function approximation

$$
\tilde{J}_{\mu}(r)=\Phi r
$$

where $\Phi$ is full rank $n \times s$ matrix with columns the basis functions, and $i$ th row denoted $\phi(i)^{\prime}$.

- Policy "improvement" to generate $\bar{\mu}$ :

$$
\bar{\mu}(i)=\arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \phi(j)^{\prime} r\right)
$$

## EVALUATION BY PROJECTED EQUATIONS

- Approximate policy evaluation by solving

$$
\Phi r=\Pi T_{\mu}(\Phi r)
$$

П: weighted Euclidean projection; special nature of the steady-state distribution weighting.

- Implementation by simulation (single long trajectory using current policy - important to make $\Pi T_{\mu}$ a contraction). LSTD, LSPE methods.
- Multistep option: Solve $\Phi r=\Pi T_{\mu}^{(\lambda)}(\Phi r)$ with

$$
T_{\mu}^{(\lambda)}=(1-\lambda) \sum_{\ell=0}^{\infty} \lambda^{\ell} T_{\mu}^{\ell+1}, \quad 0 \leq \lambda<1
$$

- As $\lambda \uparrow 1, \Pi T_{\mu}^{(\lambda)}$ becomes a contraction for any projection norm (allows changes in $\Pi$ )
- Bias-variance tradeoff

Solution of projected equation

$$
\Phi r=\Pi T^{(\lambda)}(\Phi r)
$$

## ISSUES OF POLICY IMPROVEMENT

## EXPLORATION

- 1st major issue: exploration. To evaluate $\mu$, we need to generate cost samples using $\mu$
- This biases the simulation by underrepresenting states that are unlikely to occur under $\mu$.
- As a result, the cost-to-go estimates of these underrepresented states may be highly inaccurate, and seriously impact the "improved policy" $\bar{\mu}$.
- This is known as inadequate exploration - a particularly acute difficulty when the randomness embodied in the transition probabilities is "relatively small" (e.g., a deterministic system).
- To deal with this we must change the sampling mechanism and modify the simulation formulas.
- Solve

$$
\Phi r=\bar{\Pi} T_{\mu}(\Phi r)
$$

where $\bar{\Pi}$ is projection with respect to an explorationenhanced norm [uses a weight distribution $\zeta=$ $\left.\left(\zeta_{1}, \ldots, \zeta_{n}\right)\right]$.

- $\zeta$ is more "balanced" than $\xi$ the steady-state distribution of the Markov chain of $\mu$.
- This also addresses any lack of ergodicity of $\mu$.

## EXPLORATION MECHANISMS

- One possibility: Use multiple short simulation trajectories instead of single long trajectory starting from a rich mixture of states. This is known as geometric sampling, or free-form sampling.
- By properly choosing the starting states, we enhance exploration
- The simulation formulas for $\operatorname{LSTD}(\lambda)$ and $\operatorname{LSPE}(\lambda)$ have to be modified to yield the solution of $\Phi r=\bar{\Pi} T_{\mu}^{(\lambda)}(\Phi r)$ (see the DP text)
- Another possibility: Use a modified policy to generate a single long trajectory. This is called an off-policy approach.
- Modify the transition probabilities of $\mu$ to enhance exploration
- Again the simulation formulas for $\operatorname{LSTD}(\lambda)$ and $\operatorname{LSPE}(\lambda)$ have to be modified to yield the solution of $\Phi r=\bar{\Pi} T_{\mu}^{(\lambda)}(\Phi r)$ (use of importance sampling; see the DP text)
- With larger values of $\lambda>0$ the contraction property of $\bar{\Pi} T_{\mu}^{(\lambda)}$ is maintained.
- LSTD may be used without $\bar{\Pi} T_{\mu}^{(\lambda)}$ being a contraction ... LSPE and TD require a contraction.

## POLICY ITERATION ISSUES: OSCILLATIONS

- 2nd major issue: oscillation of policies
- Analysis using the greedy partition of the space of weights $r: R_{\mu}$ is the set of parameter vectors $r$ for which $\mu$ is greedy with respect to $\tilde{J}(\cdot ; r)=\Phi r$

$$
R_{\mu}=\left\{r \mid T_{\mu}(\Phi r)=T(\Phi r)\right\} \quad \forall \mu
$$

If we use $r$ in $R_{\mu}$ the next "improved" policy is $\mu$

- If policy evaluation is exact, there is a finite number of possible vectors $r_{\mu}$, (one per $\mu$ )
- The algorithm ends up repeating some cycle of policies $\mu^{k}, \mu^{k+1}, \ldots, \mu^{k+m}$ with

$$
r_{\mu^{k}} \in R_{\mu^{k+1}}, r_{\mu^{k+1}} \in R_{\mu^{k+2}}, \ldots, r_{\mu^{k+m}} \in R_{\mu^{k}}
$$

- Many different cycles are possible

## MORE ON OSCILLATIONS/CHATTERING

- In the case of optimistic policy iteration a different picture holds (policy evaluation does not produce exactly $r_{\mu}$ )

- Oscillations of weight vector $r$ are less violent, but the "limit" point is meaningless!
- Fundamentally, oscillations are due to the lack of monotonicity of the projection operator, i.e., $J \leq J^{\prime}$ does not imply $\Pi J \leq \Pi J^{\prime}$.
- If approximate PI uses an evaluation of the form

$$
\Phi r=\left(W T_{\mu}\right)(\Phi r)
$$

with $W$ : monotone and $W T_{\mu}$ : contraction, the policies converge (to a possibly nonoptimal limit).

- These conditions hold when aggregation is used

## AGGREGATION

## PROBLEM APPROXIMATION - AGGREGATION

- Another major idea in ADP is to approximate $J^{*}$ or $J_{\mu}$ with the cost-to-go functions of a simpler problem.
- Aggregation is a systematic approach for problem approximation. Main elements:
- Introduce a few "aggregate" states, viewed as the states of an "aggregate" system
- Define transition probabilities and costs of the aggregate system, by relating original system states with aggregate states
- Solve (exactly or approximately) the "aggregate" problem by any kind of VI or PI method (including simulation-based methods)
- If $\hat{R}(y)$ is the optimal cost of aggregate state $y$, we use the approximation

$$
J^{*}(j) \approx \sum \phi_{j y} \hat{R}(y), \quad \forall j
$$

where $\phi_{j y}$ are the aggregation probabilities, encoding the "degree of membership of $j$ in the aggregate state $y "$

- This is a linear architecture: $\phi_{j y}$ are the features of state $j$

## HARD AGGREGATION EXAMPLE

- Group the original system states into subsets, and view each subset as an aggregate state
- Aggregation probs.: $\phi_{j y}=1$ if $j$ belongs to aggregate state $y$ (piecewise constant approx).

$$
\begin{aligned}
& \Phi=\left(\begin{array}{llll}
1 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{array}\right)
\end{aligned}
$$

- What should be the "aggregate" transition probs. out of $x$ ?
- Select $i \in x$ and use the transition probs. of $i$. But which $i$ should I use?
- The simplest possibility is to assume that all states $i$ in $x$ are equally likely.
- A generalization is to randomize, i.e., use "disaggregation probabilities" $d_{x i}$ : Roughly, the "degree to which $i$ is representative of $x$."

## AGGREGATION/DISAGGREGATION PROBS

- Define the aggregate system transition probabilities via two (somewhat arbitrary) choices.
- For each original system state $j$ and aggregate state $y$, the aggregation probability $\phi_{j y}$
- Roughly, the "degree of membership of $j$ in the aggregate state $y$."
- In hard aggregation, $\phi_{j y}=1$ if state $j$ belongs to aggregate state/subset $y$.
- For each aggregate state $x$ and original system state $i$, the disaggregation probability $d_{x i}$
- Roughly, the "degree to which $i$ is representative of $x$."
- Aggregation scheme is defined by the two matrices $D$ and $\Phi$. The rows of $D$ and $\Phi$ must be probability distributions.

## AGGREGATE SYSTEM DESCRIPTION

- The transition probability from aggregate state $x$ to aggregate state $y$ under control $u$
$\hat{p}_{x y}(u)=\sum_{i=1}^{n} d_{x i} \sum_{j=1}^{n} p_{i j}(u) \phi_{j y}, \quad$ or $\hat{P}(u)=D P(u) \Phi$
where the rows of $D$ and $\Phi$ are the disaggregation and aggregation probs.
- The expected transition cost is

$$
\hat{g}(x, u)=\sum_{i=1}^{n} d_{x i} \sum_{j=1}^{n} p_{i j}(u) g(i, u, j), \quad \text { or } \hat{g}=D P(u) g
$$

## AGGREGATE BELLMAN'S EQUATION

- The optimal cost function of the aggregate problem, denoted $\hat{R}$, is
$\hat{R}(x)=\min _{u \in U}\left[\hat{g}(x, u)+\alpha \sum_{y} \hat{p}_{x y}(u) \hat{R}(y)\right], \quad \forall x$ Bellman's equation for the aggregate problem.
- The optimal cost function $J^{*}$ of the original problem is approximated by $\tilde{J}$ given by

$$
\tilde{J}(j)=\sum_{y} \phi_{j y} \hat{R}(y), \quad \forall j
$$

## EXAMPLE I: HARD AGGREGATION

- Group the original system states into subsets, and view each subset as an aggregate state
- Aggregation probs.: $\phi_{j y}=1$ if $j$ belongs to aggregate state $y$.

- Disaggregation probs.: There are many possibilities, e.g., all states $i$ within aggregate state $x$ have equal prob. $d_{x i}$.
- If optimal cost vector $J^{*}$ is piecewise constant over the aggregate states/subsets, hard aggregation is exact. Suggests grouping states with "roughly equal" cost into aggregates.
- A variant: Soft aggregation (provides "soft boundaries" between aggregate states).

## EXAMPLE II: FEATURE-BASED AGGREGATION

- Important question: How do we group states together?
- If we know good features, it makes sense to group together states that have "similar features"

- A general approach for passing from a featurebased state representation to a hard aggregationbased architecture
- Essentially discretize the features and generate a corresponding piecewise constant approximation to the optimal cost function
- Aggregation-based architecture is more powerful (it is nonlinear in the features)
- ... but may require many more aggregate states to reach the same level of performance as the corresponding linear feature-based architecture

# EXAMPLE III: REP. STATES/COARSE GRID 

- Choose a collection of "representative" original system states, and associate each one of them with an aggregate state

- Disaggregation probabilities are $d_{x i}=1$ if $i$ is equal to representative state $x$.
- Aggregation probabilities associate original system states with convex combinations of representative states

$$
j \sim \sum_{y \in \mathcal{A}} \phi_{j y} y
$$

- Well-suited for Euclidean space discretization
- Extends nicely to continuous state space, including belief space of POMDP

## EXAMPLE IV: REPRESENTATIVE FEATURES

- Here the aggregate states are nonempty subsets of original system states. Common case: Each $S_{x}$ is a group of states with "similar features"

- Restrictions:
- The aggregate states/subsets are disjoint.
- The disaggregation probabilities satisfy $d_{x i}>$ 0 if and only if $i \in x$.
- The aggregation probabilities satisfy $\phi_{j y}=1$ for all $j \in y$.
- Hard aggregation is a special case: $\cup_{x} S_{x}=$ $\{1, \ldots, n\}$
- Aggregation with representative states is a special case: $S_{x}$ consists of just one state

## APPROXIMATE PI BY AGGREGATION

- Consider approximate PI for the original problem, with policy evaluation done by aggregation.
- Evaluation of policy $\mu: \tilde{J}=\Phi R$, where $R=$ $D T_{\mu}(\Phi R)$ ( $R$ is the vector of costs of aggregate states for $\mu$ ). Can be done by simulation.
- Looks like projected equation $\Phi R=\Pi T_{\mu}(\Phi R)$ (but with $\Phi D$ in place of $\Pi$ ).
- Advantage: It has no problem with oscillations.
- Disadvantage: The rows of $D$ and $\Phi$ must be probability distributions.

## ADDITIONAL ISSUES OF AGGREGATION

## ALTERNATIVE POLICY ITERATION

- The preceding PI method uses policies that assign a control to each aggregate state.
- An alternative is to use PI for the combined system, involving the Bellman equations:

$$
\begin{gathered}
R^{*}(x)=\sum_{i=1}^{n} d_{x i} \tilde{J}_{0}(i), \quad \forall x \\
\tilde{J}_{0}(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \tilde{J}_{1}(j)\right), \quad i=1, \ldots, n \\
\tilde{J}_{1}(j)=\sum_{y \in \mathcal{A}} \phi_{j y} R^{*}(y), \quad j=1, \ldots, n
\end{gathered}
$$

Original

- Simulation-based PI and VI are still possible.

## RELATION OF AGGREGATION/PROJECTION

- Compare aggregation and projected equations

$$
\Phi R=\Phi D T(\Phi R), \quad \Phi r=\Pi T(\Phi r)
$$

- If $\Phi D$ is a projection (with respect to some weighted Euclidean norm), then the methodology of projected equations applies to aggregation
- Hard aggregation case: $\Phi D$ can be verified to be projection with respect to weights $\xi_{i}$ proportional to the disaggregation probabilities $d_{x i}$
- Aggregation with representative features case: $\Phi D$ can be verified to be a semi-norm projection with respect to weights $\xi_{i}$ proportional to $d_{x i}$
- A (weighted) Euclidean semi-norm is defined by $\|J\|_{\xi}=\sqrt{\sum_{i=1}^{n} \xi_{i}(J(i))^{2}}$, where $\xi=\left(\xi_{1}, \ldots, \xi_{n}\right)$, with $\xi_{i} \geq 0$.
- If $\Phi^{\prime} \Xi \Phi$ is invertible, the entire theory and algorithms of projected equations generalizes to semi-norm projected equations [including multistep methods such as LSTD/LSPE/TD $(\lambda)]$.
- Reference: Yu and Bertsekas, "Weighted Bellman Equations and their Applications in Approximate Dynamic Programming," MIT Report, 2012.

## DISTRIBUTED AGGREGATION I

- We consider decomposition/distributed solution of large-scale discounted DP problems by hard aggregation.
- Partition the original system states into subsets $S_{1}, \ldots, S_{m}$.
- Distributed VI Scheme: Each subset $S_{\ell}$
- Maintains detailed/exact local costs
$J(i)$ for every original system state $i \in S_{\ell}$ using aggregate costs of other subsets
- Maintains an aggregate cost $R(\ell)=\sum_{i \in S_{\ell}} d_{\ell i} J(i)$
- Sends $R(\ell)$ to other aggregate states
- $J(i)$ and $R(\ell)$ are updated by VI according to

$$
J_{k+1}(i)=\min _{u \in U(i)} H_{\ell}\left(i, u, J_{k}, R_{k}\right), \quad \forall i \in S_{\ell}
$$

with $R_{k}$ being the vector of $R(\ell)$ at time $k$, and
$H_{\ell}(i, u, J, R)=\sum_{j=1}^{n} p_{i j}(u) g(i, u, j)+\alpha \sum_{j \in S_{\ell}} p_{i j}(u) J(j)$
$+\alpha \quad \sum p_{i j}(u) R\left(\ell^{\prime}\right)$
$j \in S_{\ell^{\prime}}, \ell^{\prime} \neq \ell$

## DISTRIBUTED AGGREGATION II

- Can show that this iteration involves a supnorm contraction mapping of modulus $\alpha$, so it converges to the unique solution of the system of equations in $(J, R)$

$$
\begin{aligned}
J(i)=\min _{u \in U(i)} H_{\ell}(i, u, J, R), & R(\ell)=\sum_{i \in S_{\ell}} d_{\ell i} J(i), \\
& \forall i \in S_{\ell}, \ell=1, \ldots, m .
\end{aligned}
$$

- This follows from the fact that $\left\{d_{\ell i} \mid i=\right.$ $1, \ldots, n\}$ is a probability distribution.
- View these equations as a set of Bellman equations for an "aggregate" DP problem. The difference is that the mapping $H$ involves $J(j)$ rather than $R(x(j))$ for $j \in S_{\ell}$.
- In an asynchronous version of the method, the aggregate costs $R(\ell)$ may be outdated to account for communication "delays" between aggregate states.
- Convergence can be shown using the general theory of asynchronous distributed computation, briefly described in the 2nd lecture (see the text).

# 6.231 DYNAMIC PROGRAMMING 

## LECTURE 6

## LECTURE OUTLINE

- Review of Q-factors and Bellman equations for Q-factors
- VI and PI for Q-factors
- Q-learning - Combination of VI and sampling
- Q-learning and cost function approximation
- Adaptive dynamic programming
- Approximation in policy space
- Additional topics

## REVIEW

## DISCOUNTED MDP

- System: Controlled Markov chain with states $i=1, \ldots, n$ and finite set of controls $u \in U(i)$
- Transition probabilities: $p_{i j}(u)$

- Cost of a policy $\pi=\left\{\mu_{0}, \mu_{1}, \ldots\right\}$ starting at state $i$ :

$$
J_{\pi}(i)=\lim _{N \rightarrow \infty} E\left\{\sum_{k=0}^{N} \alpha^{k} g\left(i_{k}, \mu_{k}\left(i_{k}\right), i_{k+1}\right) \mid i=i_{0}\right\}
$$

with $\alpha \in[0,1)$

- Shorthand notation for DP mappings

$$
\begin{aligned}
& (T J)(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha J(j)), \quad i=1, \ldots, n, \\
& \left(T_{\mu} J\right)(i)=\sum_{j=1}^{n} p_{i j}(\mu(i))(g(i, \mu(i), j)+\alpha J(j)), \quad i=1, \ldots, n
\end{aligned}
$$

## BELLMAN EQUATIONS FOR $Q$-FACTORS

- The optimal $Q$-factors are defined by

$$
Q^{*}(i, u)=\sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J^{*}(j)\right), \quad \forall(i, u)
$$

- Since $J^{*}=T J^{*}$, we have $J^{*}(i)=\min _{u \in U(i)} Q^{*}(i, u)$ so the optimal $Q$-factors solve the equation

$$
Q^{*}(i, u)=\sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \min _{u^{\prime} \in U(j)} Q^{*}\left(j, u^{\prime}\right)\right)
$$

- Equivalently $Q^{*}=F Q^{*}$, where

$$
(F Q)(i, u)=\sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \min _{u^{\prime} \in U(j)} Q\left(j, u^{\prime}\right)\right)
$$

- This is Bellman's Eq. for a system whose states are the pairs $(i, u)$
- Similar mapping $F_{\mu}$ and Bellman equation for a policy $\mu$ : $Q_{\mu}=F_{\mu} Q_{\mu}$

# BELLMAN EQ FOR $Q$-FACTORS OF A POLICY 

State-Control Pairs: Fixed Policy $\mu$

- Q-factors of a policy $\mu$ : For all $(i, u)$

$$
Q_{\mu}(i, u)=\sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha Q_{\mu}(j, \mu(j))\right)
$$

Equivalently $Q_{\mu}=F_{\mu} Q_{\mu}$, where

$$
\left(F_{\mu} Q\right)(i, u)=\sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha Q(j, \mu(j)))
$$

- This is a linear equation. It can be used for policy evaluation.
- Generally VI and PI can be carried out in terms of Q-factors.
- When done exactly they produce results that are mathematically equivalent to cost-based VI and PI.

## WHAT IS GOOD AND BAD ABOUT Q-FACTORS

- All the exact theory and algorithms for costs applies to Q-factors
- Bellman's equations, contractions, optimality conditions, convergence of VI and PI
- All the approximate theory and algorithms for costs applies to Q-factors
- Projected equations, sampling and exploration issues, oscillations, aggregation
- A MODEL-FREE (on-line) controller implementation
- Once we calculate $Q^{*}(i, u)$ for all $(i, u)$,

$$
\mu^{*}(i)=\arg \min _{u \in U(i)} Q^{*}(i, u), \quad \forall i
$$

- Similarly, once we calculate a parametric approximation $\tilde{Q}(i, u ; r)$ for all $(i, u)$,

$$
\tilde{\mu}(i)=\arg \min _{u \in U(i)} \tilde{Q}(i, u ; r), \quad \forall i
$$

- The main bad thing: Greater dimension and more storage! (It can be used for large-scale problems only through aggregation, or other approximation.)

## Q-LEARNING

## Q-LEARNING

- In addition to the approximate PI methods adapted for Q-factors, there is an important additional algorithm:
- Q-learning, a sampled form of VI (a stochastic iterative algorithm).
- Q-learning algorithm (in its classical form):
- Sampling: Select sequence of pairs $\left(i_{k}, u_{k}\right)$ [use any probabilistic mechanism for this, but all $(i, u)$ are chosen infinitely often].
- Iteration: For each $k$, select $j_{k}$ according to $p_{i_{k} j}\left(u_{k}\right)$. Update just $Q\left(i_{k}, u_{k}\right)$ :

$$
\begin{aligned}
Q_{k+1}\left(i_{k}, u_{k}\right) & =\left(1-\gamma_{k}\right) Q_{k}\left(i_{k}, u_{k}\right) \\
+ & \gamma_{k}\left(g\left(i_{k}, u_{k}, j_{k}\right)+\alpha \min _{u^{\prime} \in U\left(j_{k}\right)} Q_{k}\left(j_{k}, u^{\prime}\right)\right)
\end{aligned}
$$

Leave unchanged all other Q-factors.

- Stepsize conditions: $\gamma_{k} \downarrow 0$
- We move $Q(i, u)$ in the direction of a sample of

$$
(F Q)(i, u)=\sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \min _{u^{\prime} \in U(j)} Q\left(j, u^{\prime}\right)\right)
$$

## NOTES AND QUESTIONS ABOUT Q-LEARNING

$$
\begin{aligned}
& Q_{k+1}\left(i_{k}, u_{k}\right)=\left(1-\gamma_{k}\right) Q_{k}\left(i_{k}, u_{k}\right) \\
&+\gamma_{k}\left(g\left(i_{k}, u_{k}, j_{k}\right)+\alpha \min _{u^{\prime} \in U\left(j_{k}\right)} Q_{k}\left(j_{k}, u^{\prime}\right)\right)
\end{aligned}
$$

- Model free implementation. We just need a simulator that given $(i, u)$ produces next state $j$ and cost $g(i, u, j)$
- Operates on only one state-control pair at a time. Convenient for simulation, no restrictions on sampling method. (Connection with asynchronous algorithms.)
- Aims to find the (exactly) optimal Q-factors.
- Why does it converge to $Q^{*}$ ?
- Why can't I use a similar algorithm for optimal costs (a sampled version of VI)?
- Important mathematical (fine) point: In the $Q$ factor version of Bellman's equation the order of expectation and minimization is reversed relative to the cost version of Bellman's equation:

$$
J^{*}(i)=\min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha J^{*}(j)\right)
$$

## CONVERGENCE ASPECTS OF Q-LEARNING

- $Q$-learning can be shown to converge to true/exact $Q$-factors (under mild assumptions).
- The proof is sophisticated, based on theories of stochastic approximation and asynchronous algorithms.
- Uses the fact that the Q-learning map $F$ :

$$
(F Q)(i, u)=E_{j}\left\{g(i, u, j)+\alpha \min _{u^{\prime}} Q\left(j, u^{\prime}\right)\right\}
$$

is a sup-norm contraction.

- Generic stochastic approximation algorithm:
- Consider generic fixed point problem involving an expectation:

$$
x=E_{w}\{f(x, w)\}
$$

- Assume $E_{w}\{f(x, w)\}$ is a contraction with respect to some norm, so the iteration

$$
x_{k+1}=E_{w}\left\{f\left(x_{k}, w\right)\right\}
$$

converges to the unique fixed point

- Approximate $E_{w}\{f(x, w)\}$ by sampling

## STOCH. APPROX. CONVERGENCE IDEAS

- Generate a sequence of samples $\left\{w_{1}, w_{2}, \ldots\right\}$, and approximate the convergent fixed point iteration $x_{k+1}=E_{w}\left\{f\left(x_{k}, w\right)\right\}$
- At each iteration $k$ use the approximation

$$
x_{k+1}=\frac{1}{k} \sum_{t=1}^{k} f\left(x_{k}, w_{t}\right) \approx E_{w}\left\{f\left(x_{k}, w\right)\right\}
$$

- A major flaw: it requires, for each $k$, the computation of $f\left(x_{k}, w_{t}\right)$ for all values $w_{t}, t=1, \ldots, k$.
- This motivates the more convenient iteration

$$
x_{k+1}=\frac{1}{k} \sum_{t=1}^{k} f\left(x_{t}, w_{t}\right), \quad k=1,2, \ldots
$$

that is similar, but requires much less computation; it needs only one value of $f$ per sample $w_{t}$.

- By denoting $\gamma_{k}=1 / k$, it can also be written as

$$
x_{k+1}=\left(1-\gamma_{k}\right) x_{k}+\gamma_{k} f\left(x_{k}, w_{k}\right), \quad k=1,2, \ldots
$$

- Compare with Q-learning, where the fixed point problem is $Q=F Q$

$$
(F Q)(i, u)=E_{j}\left\{g(i, u, j)+\alpha \min _{u^{\prime}} Q\left(j, u^{\prime}\right)\right\}
$$

## $Q$-LEARNING COMBINED WITH OPTIMISTIC PI

- Each Q-learning iteration requires minimization over all controls $u^{\prime} \in U\left(j_{k}\right)$ :

$$
\begin{aligned}
& Q_{k+1}\left(i_{k}, u_{k}\right)=\left(1-\gamma_{k}\right) Q_{k}\left(i_{k}, u_{k}\right) \\
&+\gamma_{k}\left(g\left(i_{k}, u_{k}, j_{k}\right)+\alpha \min _{u^{\prime} \in U\left(j_{k}\right)} Q_{k}\left(j_{k}, u^{\prime}\right)\right)
\end{aligned}
$$

- To reduce this overhead we may consider replacing the minimization by a simpler operation using just the "current policy" $\mu_{k}$
- This suggests an asynchronous sampled version of the optimistic PI algorithm which policy evaluates by

$$
Q_{k+1}=F_{\mu^{k}}^{m_{k}} Q_{k},
$$

and policy improves by $\mu^{k+1}(i) \in \arg \min _{u \in U(i)} Q_{k+1}(i, u)$

- This turns out not to work (counterexamples by Williams and Baird, which date to 1993), but a simple modification of the algorithm is valid
- See a series of papers starting with
D. Bertsekas and H. Yu, "Q-Learning and Enhanced Policy Iteration in Discounted Dynamic Programming," Math. of OR, Vol. 37, 2012, pp. 66-94

## $Q$-FACTOR APPROXIMATIONS

- We introduce basis function approximation:

$$
\tilde{Q}(i, u ; r)=\phi(i, u)^{\prime} r
$$

- We can use approximate policy iteration and LSTD/LSPE for policy evaluation
- Optimistic policy iteration methods are frequently used on a heuristic basis
- An extreme example: Generate trajectory $\left\{\left(i_{k}, u_{k}\right) \mid\right.$ $k=0,1, \ldots\}$ as follows.
- At iteration $k$, given $r_{k}$ and state/control $\left(i_{k}, u_{k}\right)$ :
(1) Simulate next transition $\left(i_{k}, i_{k+1}\right)$ using the transition probabilities $p_{i_{k} j}\left(u_{k}\right)$.
(2) Generate control $u_{k+1}$ from

$$
u_{k+1}=\arg \min _{u \in U\left(i_{k+1}\right)} \tilde{Q}\left(i_{k+1}, u, r_{k}\right)
$$

(3) Update the parameter vector via

$$
r_{k+1}=r_{k}-(\text { LSPE or TD-like correction })
$$

- Complex behavior, unclear validity (oscillations, etc). There is solid basis for an important special case: optimal stopping (see text)

## BELLMAN EQUATION ERROR APPROACH

- Another model-free approach for approximate evaluation of policy $\mu$ : Approximate $Q_{\mu}(i, u)$ with $\tilde{Q}_{\mu}\left(i, u ; r_{\mu}\right)=\phi(i, u)^{\prime} r_{\mu}$, obtained from

$$
r_{\mu} \in \arg \min _{r}\left\|\Phi r-F_{\mu}(\Phi r)\right\|_{\xi}^{2}
$$

where $\|\cdot\|_{\xi}$ is Euclidean norm, weighted with respect to some distribution $\xi$.

- Implementation for deterministic problems:
(1) Generate a large set of sample pairs $\left(i_{k}, u_{k}\right)$, and corresponding deterministic costs $g\left(i_{k}, u_{k}\right)$ and transitions $\left(j_{k}, \mu\left(j_{k}\right)\right)$ (a simulator may be used for this).
(2) Solve the linear least squares problem:
$\min _{r} \sum_{\left(i_{k}, u_{k}\right)}\left|\phi\left(i_{k}, u_{k}\right)^{\prime} r-\left(g\left(i_{k}, u_{k}\right)+\alpha \phi\left(j_{k}, \mu\left(j_{k}\right)\right)^{\prime} r\right)\right|^{2}$
- For stochastic problems a similar (more complex) least squares approach works. It is closely related to LSTD (but less attractive; see the text).
- Because this approach is model-free, it is often used as the basis for adaptive control of systems with unknown dynamics.

## ADAPTIVE CONTROL BASED ON ADP

## LINEAR-QUADRATIC PROBLEM

- System: $x_{k+1}=A x_{k}+B u_{k}, x_{k} \in \Re^{n}, u_{k} \in \Re^{m}$
- Cost: $\sum_{k=0}^{\infty}\left(x_{k}^{\prime} Q x_{k}+u_{k}^{\prime} R u_{k}\right), Q \geq 0, R>0$
- Optimal policy is linear: $\mu^{*}(x)=L x$
- The Q-factor of each linear policy $\mu$ is quadratic:

$$
Q_{\mu}(x, u)=\left(\begin{array}{ll}
x^{\prime} & u^{\prime} \tag{*}
\end{array}\right) K_{\mu}\binom{x}{u}
$$

- We will consider $A$ and $B$ unknown
- We represent Q-factors using as basis functions all the quadratic functions involving state and control components

$$
x^{i} x^{j}, \quad u^{i} u^{j}, \quad x^{i} u^{j}, \quad \forall i, j
$$

These are the "rows" $\phi(x, u)^{\prime}$ of $\Phi$

- The Q -factor $Q_{\mu}$ of a linear policy $\mu$ can be exactly represented within the approximation subspace:

$$
Q_{\mu}(x, u)=\phi(x, u)^{\prime} r_{\mu}
$$

where $r_{\mu}$ consists of the components of $K_{\mu}$ in (*)

## PI FOR LINEAR-QUADRATIC PROBLEM

- Policy evaluation: $r_{\mu}$ is found by the Bellman error approach

$$
\min _{r} \sum_{\left(x_{k}, u_{k}\right)}\left|\phi\left(x_{k}, u_{k}\right)^{\prime} r-\left(x_{k}^{\prime} Q x_{k}+u_{k}^{\prime} R u_{k}+\phi\left(x_{k+1}, \mu\left(x_{k+1}\right)\right)^{\prime} r\right)\right|^{2}
$$

where $\left(x_{k}, u_{k}, x_{k+1}\right)$ are many samples generated by the system or a simulator of the system.

- Policy improvement:

$$
\bar{\mu}(x) \in \arg \min _{u}\left(\phi(x, u)^{\prime} r_{\mu}\right)
$$

- Knowledge of $A$ and $B$ is not required
- If the policy evaluation is done exactly, this becomes exact PI, and convergence to an optimal policy can be shown
- The basic idea of this example has been generalized and forms the starting point of the field of adaptive dynamic programming
- This field deals with adaptive control of continuousspace (possibly nonlinear) dynamic systems, in both discrete and continuous time

## APPROXIMATION IN POLICY SPACE

## APPROXIMATION IN POLICY SPACE

- We parametrize policies by a vector $r=\left(r_{1}, \ldots, r_{s}\right)$ (an approximation architecture for policies).
- Each policy $\tilde{\mu}(r)=\{\tilde{\mu}(i ; r) \mid i=1, \ldots, n\}$ defines a cost vector $J_{\tilde{\mu}(r)}$ (a function of $r$ ).
- We optimize some measure of $J_{\tilde{\mu}(r)}$ over $r$.
- For example, use a random search, gradient, or other method to minimize over $r$

$$
\sum_{i=1}^{n} \xi_{i} J_{\tilde{\mu}(r)}(i),
$$

where $\xi_{1}, \ldots, \xi_{n}$ are some state-dependent weights.

- An important special case: Introduce cost approximation architecture $V(i ; r)$ that defines indirectly the parametrization of the policies
$\tilde{\mu}(i ; r)=\arg \min _{u \in U(i)} \sum_{j=1}^{n} p_{i j}(u)(g(i, u, j)+\alpha V(j ; r)), \forall i$
- This introduces state features into approximation in policy space.
- A policy approximator is called an actor, while a cost approximator is also called a critic. An actor and a critic may coexist.

## APPROXIMATION IN POLICY SPACE METHODS

- Random search methods are straightforward and have scored some impressive successes with challenging problems (e.g., tetris).
- At a given point/r they generate a random collection of neighboring $r$. They search within the neighborhood for better points.
- Many variations (the cross entropy method is one).
- They are very broadly applicable (to discrete and continuous search spaces).
- They are idiosynchratic.
- Gradient-type methods (known as policy gradient methods) also have been used extensively.
- They move along the gradient with respect to $r$ of

$$
\sum_{i=1}^{n} \xi_{i} J_{\tilde{\mu}(r)}(i)
$$

- There are explicit gradient formulas which can be approximated by simulation.
- Policy gradient methods generally suffer by slow convergence, local minima, and excessive simulation noise.

## COMBINATION WITH APPROXIMATE PI

- Another possibility is to try to implement PI within the class of parametrized policies.
- Given a policy/actor $\mu\left(i ; r_{k}\right)$, we evaluate it (perhaps approximately) with a critic that produces $\tilde{J}_{\mu}$, using some policy evaluation method.
- We then consider the policy improvement phase
$\bar{\mu}(i) \in \arg \min _{u} \sum_{j=1}^{n} p_{i j}(u)\left(g(i, u, j)+\alpha \tilde{J}_{\mu}(j)\right), \quad \forall i$
and do it approximately via parametric optimization
$\min _{r} \sum_{i=1}^{n} \xi_{i} \sum_{j=1}^{n} p_{i j}(\bar{\mu}(i ; r))\left(g(i, \bar{\mu}(i ; r), j)+\alpha \tilde{J}_{\mu}(j)\right)$ where $\xi_{i}$ are some weights.
- This can be attempted by a gradient-type method in the space of the parameter vector $r$.
- Schemes like this have been extensively applied to continuous-space deterministic problems.
- Many unresolved theoretical issues, particularly for stochastic problems.

## FINAL WORDS

## TOPICS THAT WE HAVE NOT COVERED

- Extensions to discounted semi-Markov, stochastic shortest path problems, average cost problems, sequential games ...
- Extensions to continuous-space problems
- Extensions to continuous-time problems
- Adaptive DP - Continuous-time deterministic optimal control. Approximation of cost function derivatives or cost function differences
- Random search methods for approximate policy evaluation or approximation in policy space
- Basis function adaptation (automatic generation of basis functions, optimal selection of basis functions within a parametric class)
- Simulation-based methods for general linear problems, i.e., solution of linear equations, linear least squares, etc - Monte-Carlo linear algebra

## CONCLUDING REMARKS

- There is no clear winner among ADP methods - There is interesting theory in all types of methods (which, however, does not provide ironclad performance guarantees)
- There are major flaws in all methods:
- Oscillations and exploration issues in approximate PI with projected equations
- Restrictions on the approximation architecture in approximate PI with aggregation
- Flakiness of optimization in policy space approximation
- Yet these methods have impressive successes to show with enormously complex problems, for which there is often no alternative methodology
- There are also other competing ADP methods (rollout is simple, often successful, and generally reliable; approximate LP is worth considering)
- Theoretical understanding is important and nontrivial
- Practice is an art and a challenge to our creativity!

## THANK YOU
